GEIKIE'S "LIFE OF MURCHISON"

Life of Sir Roderick I. Murchison, Bart., F.R.S. etc. Based on his Journals and Letters. With Notices of his Scientific Contemporaries and a Sketch of the Rise and Growth of Palæozoic Geology in Britain. By Archibald Geikie, LL.D., F.R.S., Director of H.M. Geological Survey of Scotland, and Murchison Professor of Geology and Mineralogy in the University of Edinburgh. 2 vols. Illustrated with Portraits and Woodcuts. (London: John Murray, 1875.)

TO have before us in detail, and reflected as in a mirror of his own notes and correspondence, the story of the life of one who has taken a foremost place in the ranks of science, is a matter of no little interest. We want to know as much as we can of the kind of qualities that go to make a successful man of science, and of the circumstances which have enabled him to be useful to the world. Such information may be obtained either by categorical questions addressed to such men during life, after the manner of Mr. Francis Galton's work lately reviewed in these columns,* in which we have the advantage of numbers for comparison; or by the more detailed story of the life of individuals, from which we can gather for ourselves the answers to our questions, with all the additional light thrown upon them by surrounding circumstances.

Such a story is that presented to us by Prof. Geikie of the life of Sir Roderick Murchison, whom no one will deny to have occupied a foremost place, and to have contributed valuable and lasting materials to the sciences to which he devoted himself. Many, indeed, and fruitful are the teachings of such a life as this, and some of them are well pointed out by the author in his concluding lines.

Nor is the interest of the work confined to this. Not only was Murchison eminent in science, but he ranks among the founders of one of its most recent branches—Geology; and hence, though in later years his name has been more prominently connected in the public mind with Geography, it is as a geologist alone that he will be known to posterity; and the study of his life is an examination of the way in which some of the chief corner-stones of Geology were laid.

Prof. Geikie has performed his promised task in an admirable manner. It must be remembered that he was asked by the subject himself to undertake the work, and the materials out of which he was to develop it were placed in his hands; and under these circumstances he must necessarily be guided partly by the probable wishes of the subject, and partly by the nature of his material; and if it be a biographer's duty to "hold a mirror up to nature," there can be no doubt that Prof. Geikie has admirably done so. The scenes and circumstances that formed so large a part of the acted life may well occupy an equally large share in the written life, however much geologists or students of human nature might wish for different matter.

We have no doubt that Prof. Geikie would have preferred to write such a life as we have indicated, and he has done his best to escape from a "narrative devoted merely to the personal events of Sir Roderick Murchison's life;" but in loyalty to his friend he felt bound, no doubt, to follow his desires rather than his own. Those who are acquainted with Prof. Geikie's other writings need not be told that this is written with admirable perspicuity, and his candour and ingenuousness are above all praise. There is no false colouring here; we see Murchison as he was; what was good not exaggerated, but duly brought forward; what was bad (and who has not faults?) by no means palliated, though, where possible, accounted for. These are undoubtedly the great merits of the work, and ought to inspire thorough confidence where it touches on matters of controversy.

The Life before us gives admirable means of perceiving the exact relation of Sir Roderick Murchison to the science of Geology, and the qualities and circumstances which enabled him to stand in that relation. There are times in the history of a Science, as in the history of a Nation, when some definite work has to be done, and it is

* NATURE, vol. xi. p. 161.

done, as we may say, through some power of natural selection, by one whose qualities are adapted for that purpose and for that alone, and whose greatness consists in being exactly fitted in that respect to the time in which he lives, and it may be in nothing besides. Before we consider the relation which Murchison held in this way to Geology, we may pass in review the chief incidents of his life as detailed for us in these volumes.

Sir Roderick was descended from a sturdy Highland stock, whose courage and perseverance he inherited, but who contributed no further to his fortune. His father was a surgeon, who, after making a fortune in India, returned to his native land and bought the estate of Tarradale, in the eastern part of the county of Ross, where Roderick was born on Feb. 19, 1792. When the boy was only three years old the family removed to Bath, where the father died in 1796. Three years after, Roderick's mother married a second time, and the boy, at the age of seven years, was sent to the grammar school of Durham. Here he seems to have learnt little but mischief; but educational requirements were not great in those days, and he probably knew at the end of his six years as much as most of his contemporaries. Certainly his education here had no manner of influence, as far as we can see, on his future career; and the absence of scientific culture in youth, if it did not prevent him from rising to greatness and doing good work, would most decidedly have done so had he been thrown into other circumstances and lived in days like our own, and it certainly confined him to the limits of a geological worker instead of allowing him to become a geological philosopher.

After leaving Durham, and visiting his uncle, General Mackenzie, who persuaded him he would make a good soldier, he was sent to the military college at Great Marlow. The two years he spent here cannot be said to have been without use to him, for if he learnt but little from books, he was forced to undergo the more special training for a soldier's career, which in after life had a solidifying effect on his character. At this time his uncle wrote of him: "He is a charming boy, manly, sensible, generous, warm-hearted. I think he has talents to make a figure in any profession." At the age of fifteen he was gazetted Ensign in the 36th Regiment, which, after picking up some scraps of knowledge in Edinburgh, he joined in Ireland. He had not long to wait for work, for in the following year (1808) his regiment was ordered to the Peninsula, and he received his "baptism of fire" at the battle of Vimieira. We need scarcely say of any English soldier that he behaved with bravery in battle, and fortitude under trying circumstances: but, after a short display of these qualities, a retreat was ordered from Corunna, and Murchison returned home, being nearly wrecked in the transport. Though he joined his uncle Mackenzie as aide-de-camp in the following year, he never again succeeded in getting into active service, and this induced him, after eight years' career, to retire from the army.

Murchison was evidently a keen soldier, and it seems probable that, had he found adequate scope for the irrepressible energy of his character in this direction, Geology would have lost his services. At the age of twenty-three, on August 29, 1815, he married Miss Charlotte Hugonin, daughter of General Hugonin, of Nursted House, Hampshire; an event which had a more than usual influence on his future career. In the first place, her fortune, combined with his own, enabled him to devote himself to any pursuit he might take up, without having the distractions of bread-winning routine duties, and in later years to keep up that state and hospitality which made him the representative of science in the upper circles of society. But also, and to her honour, she exercised a most salutary personal influence over him, almost imperceptible, but always in the right direction. Prof. Geikie says, "to his wife he owed his fame;" but a perusal of his life assures us that this must be taken in a very qualified sense. Such a steady attachment to science as he showed for more than forty years argues a natural bent that way that would sooner or later have been developed under any circumstances; yet at one time certainly she was his "*better* half," and her influence deserves all admiration. It was soon after his marriage that he retired from the army, chiefly to avoid introducing his wife to the monotony of barrack life. What pursuit was he to follow now? Something it must be that, while it would not engross too much time and effort, would leave him plenty of scope for the satisfaction of that muscular energy which was continually craving for some adequate outlet. Should he become a country parson, trudging for miles over the wild country side to visit some outlying houses, varying his duties occasionally by a fox-hunt or a day's shooting? He actually thought of this; but his creed, as given in his own words by his biographer, shows that this was really an impossible solution of the question. So he tried travel; and for two years roamed over Italy and examined the treasures of art with a quickly ripening critical eye. His enthusiasm in this pursuit, which was quite new to him, proved how vast was his energy, and that it only required guidance into a suitable channel to accomplish valuable work. But he found out in time that art was not his calling; and, tired of continental travel, he brought back his wife to England. Then there was nothing but fox-hunting that he could think of to employ his energies; so he spent five of the best years of his life, from twenty-six to thirty-one, in this important occupation, and succeeded in gaining the glorious distinction of being the best rider in his neighbourhood.

But the wild oats were sown at last, and partly from *ennui*, partly from meeting with Sir Humphry Davy, and greatly from the influence of his wife, he once more looked the question in the face—Was there no employment that would be worthy of a man of energy, that would require and repay his enthusiasm?

At that time (1825) Geology was in need of such a man as he. Some few years before the Geological Society had been started, and its principle was this: "In the present state of geological science, facts are more wanted than theories." Now, while the facts of most other sciences are obtained in the closet, many of those of geology are to be gathered in the field. Prof. Geikie gives in this connection a pleasant outline of the state of theoretical geology of the time, on some details of which there may possibly be difference of opinion, but it is certain that no sound progress could be made on account of the backwardness of stratigraphical geology; almost

the only good work as yet done in this direction being that of Wm. Smith—a man considerably like Murchison in character, though in a lower walk of life, and who had mapped and arranged most of what we now call secondary rocks. Much remained yet to be done both among these and above them, but below them was a perfect blank. No one had yet attempted to attack the monster "Grauwacke" in his fastnesses. It was not, however, to be conquered by a tyro, and it was only after minor attempts elsewhere that Murchison made the assault upon it from above, while Sedgwick undermined it from below.

Murchison's life hitherto has not been such as to lead us to expect much of him; but a study of his biography and a knowledge of his works prove that we must from this time see him in a different light; without indeed the advantages of early training, yet earnestly doing his best under the circumstances to advance the cause of science in that way in which alone he could hope to do so. He was one of those who

> "rise
> On stepping-stones of their dead selves
> To higher things;"

and we next hear of him as a diligent student of Brande, Buckland, Webster, and Wollaston, and very shortly following out, at the suggestion of others, some new lines of inquiry, where information was wanted. The discussion of these works we will postpone for the present, and pass on to the sketch of his life henceforth as detailed for us so clearly by Prof. Geikie.

His first excursion was in the summer of 1825, when he was accompanied by his wife, and made a tour of nine weeks on the south coast, from the Isle of Wight into Devon and Cornwall. "Driving, boating, walking, or scrambling, the enthusiastic pair signalised their first geological tour by a formidable amount of bodily toil."

Murchison associated himself early in his geological career with Sedgwick, with whom he had many a happy and profitable tour, the first of which took place in 1827, when they went together to the Island of Arran. Murchison's summers for many years now were spent in the field, while his winters in London were given to society, and to the work of the Secretary of the Geological Society, which he voluntarily undertook. It was not till 1831 that he first broke ground in "Siluria," the results of which appeared after many delays, in 1838, in the well-known "Silurian System." He was not content with work in England only, but quite as often traversed the Continent, bringing home results, and enjoying the society of the chiefs of geology abroad. No sooner was his first work well off his hands than he began to contemplate an excursion to Russia to trace the same rocks there, and having been partially successful in 1840, the next year he surveyed the whole of the Ural Mountains under the auspices of the Emperor, and with the assistance of Count Keyserling and De Verneuil, the results of which survey appeared in 1845 in the magnificent work entitled "Geology of Russia and the Ural Mountains."

From this time Murchison's position in the ranks of geologists was secure. How did he use it? To this there can be but one answer. He used all the influence his position gave him for the advancement of science. His personal energies never flagged; no summer passed but he did good work, which now forms part of the common property of geologists. Each autumn saw him enthusiastically engaged in the work of the British Association, of which he was president in 1846, and in which he ever continued to take a genuine interest. During these years his devotion to the Geographical Society increased, and, as our readers know, he was in the end regarded as so indispensable to its prosperity, that for the last ten years of his life he was president.

This Society was almost of his own making, for it was a very different thing when he joined it to what it was when he died; and perhaps some little feeling of jealousy may be entertained by geologists at the apparent transference of his affections. But it should be remembered that throughout his career Murchison was a pioneer. His works are all masterly outlines of fresh fields; and when by the time that infirmities in any case would prevent him from doing much field-work, he found a large band of geologists working at details throughout Europe. No room was left for such preliminary investigations as his, unless he went by proxy, so to speak, to countries far away; and in the end he was strictly serving Geology, by encouraging Physical Geography; for the former is impossible without the foundation of the latter being laid.

As Director-General of the Geological Survey, a post which he held from the death of Sir H. De la Beche in 1855 until his own decease in 1871, he earned the gratitude of geologists by the enlarged scope he persuaded the Government to give to it, and its consequent rapid and invaluable work; while in this and in other ways he was always ready and anxious to help forward any rising worker in the field.

Into further details of his life—how honours were poured on him from all sides, which he received with avidity; how he never failed to enjoy the delights of society; how he obtained a Geographical Section at the British Association; how he endowed a professorship of Geology—into these we cannot enter more fully, but must refer the reader to the book itself, where they are all admirably set forth.

The last words of Prof. Geikie on the character of Sir Roderick Murchison are very good. He traces the success of his career and the value of his life to three main sources. "Foremost we would place his vigorous energy, his unwearied and almost reckless activity. He never seemed to be without a definite and well-planned task." "Another leading feature in his character . . . was shrewd common sense and knowledge of the world;" and "there was still another characteristic which secured to Murchison the esteem as well as the respect of his fellow-men—his thorough kindliness and goodness of heart." Every one of these features is amply illustrated in the details of his life; and though other features, perhaps not quite so imitable, may strike us on its perusal, yet these stand out in the foreground, and teach the ever-required lesson that industry and energy are the invariable forerunners of success. (*To be continued.*)

THE FLORA OF BRITISH INDIA

The Flora of British India. By Dr. J. D. Hooker, C.B., assisted by various Botanists. Vol. I. Ranunculaceæ to Sapindaceæ. (London: Reeve and Co.)

THE completion of the first volume of the Flora of India is an event of no small importance in descriptive botany. That India should be almost the last of our

possessions whose vegetable wealth botanists have undertaken to describe in a systematic order, is due to various causes, not the least of which is the enormous labour of collecting and sifting the scattered literature bearing on this subject. The books and short papers on the botany of various parts of India are exceedingly numerous, and several works have been commenced never to be completed. Dr. Hooker himself, in conjunction with Dr. T. Thomson, published some years ago the first volume of a Flora of India based upon a more elaborate plan than that of the work now in progress, which departs from that of the other Colonial Floras, Hooker's "Student's Flora of the British Islands" having served as a model.

In addition to British India proper, this work embraces the territories of the Malayan Peninsula, Kashmir, and Western Thibet; but Afghanistan and Baluchistan, having been taken up by Boissier in his "Flora Orientalis," are not included. The total area under investigation exceeds a million square miles, exhibiting every variety of climate, soil, and other conditions, and ranging from the sea-level to an altitude of 19,000 feet, which is about the upper limit of flowering plants. Dr. Hooker computes the total number of species growing within this area at 12 to 14,000, which is doubtless not very wide of the mark, judging from the number reached up to the end of the *Sapindaceæ*.

In the first place we will give a glance at the contents of the present volume, which forms about a sixth part of the whole work. Exclusive of an index of forty pages, it extends to about 700 pages, and includes descriptions of 2,250 species under 442 genera, belonging to forty-four natural orders. These figures do not take in introduced plants incidentally mentioned or fully described. Contrasting these numbers with those afforded by the flora of tropical Africa up to the end of the *Sapindaceæ*, we obtain some idea of the relative richness of the vegetation of tropical Asia, especially if we bear in mind that the area of tropical Africa is more than six times the extent of India. True, African vegetation is not so well known, but future discoveries in the respective countries will probably not materially alter the proportions. The numbers for tropical Africa, which we have added up in Oliver's "Flora of Tropical Africa," are 945 species in 250 genera, and forty-five natural orders. It will be seen that the number of natural orders is almost the same, one more being represented in Africa than in India. A very large proportion of the species enumerated in the volume before us are exclusively Asiatic; we have not made an exact calculation, but should estimate it at ninety per cent. Of the 442 genera, 164 are, so far as our present knowledge goes, peculiar to Asia. The greater part of the peculiar genera are tropical, and many of these, doubtless, still remain to be discovered in New Guinea and tropical Australia. The mountains of Northern India have furnished our parks and gardens with many useful and ornamental trees, &c.; e.g., *Cedrus Deodara* and *Pinus excelsa*; and many others might be introduced with a view to profit or pleasure. In most cases, where possible, Dr. Hooker gives the altitudes at which the species are known to occur; but of course this part must still be imperfect. We have made a list of those species reported as growing *above* 10,000 feet, and it includes nearly 250 species, or about a tenth part of the whole number. These belong chiefly to the *Ranunculaceæ*, *Cruciferæ*, and *Caryophylleæ*, and contain a large number of endemic species; the remainder being chiefly common either to Siberia or the Alps of Southern and plains of Northern Europe, including many common British plants. We will not trouble the reader with many more figures, but we may select a few more to give a general idea of the vegetation up to the point reached in this volume. Taking two or three examples of those orders consisting mainly of herbaceous plants or climbing shrubs, we have *Ranunculaceæ*, 115 species, or 5·2 per cent; *Cruciferæ*, 137 species, or about 6 per cent.; *Caryophylleæ*, 104 species, or 4·6 per cent.; and *Geraniaceæ*, 165 species, or 7·3 per cent. Turning to the woody orders which characterise the tropical and sub-tropical regions, we have *Anonaceæ*, 190 species, or about 8·5 per cent.; *Dipterocarpeæ* (an almost exclusively Asiatic family), 92 species, or about 4 per cent.; *Guttiferæ* 61, *Tiliaceæ* 109, *Meliaceæ* 83, *Olacineæ* 66, *Celastrineæ* 105, and *Sapindaceæ* 70 species. Among genera numerous in species we may mention *Capparis* *Garcinia*, *Grewia*, *Impatiens*, and *Vitis*. Considerably more than a hundred species of *Impatiens* are described, and about 75 of *Vitis*; seven of the former genus ascend above 10,000 feet, and nearly all of them are very restricted in their geographical area. In tropical Africa there is about the same number of species of *Vitis*, but only one or two are common to both regions, the others being endemic.

So far we have confined ourselves to an attempt to indicate the interest of the work as a contribution to phytogeography; its usefulness in applied botany cannot be over-estimated. It would not be difficult, it is true, to point out a great many little defects and inequalities in elaborating the materials at their disposal by the different contributors. But those whose experience is least in this branch of botany are aware of the difficulties encountered at every step. In the first place, the limitation of species must be more or less arbitrary, and it is by no means an easy task to settle the limits, in this case especially, on account of the large number of forms described as species by botanists of all nations in innumerable books and journals. The view here taken of species is a broad one; hence we find that there is an average of two synonyms to each species, and in some instances the array of names is something quite formidable. Of course many of these synonyms result from individual views respecting generic limits. As to genera, there is little deviation from Hooker and Bentham's "Genera Plantarum," though an examination of a large number of specimens has frequently necessitated a modification of the diagnoses of certain genera. As to "polymorphous species," the forms readily distinguished are briefly characterised as varieties; but it is assumed that the extreme forms collected under one species are united by every intermediate gradation, so that it is not possible in practice to say to which variety some forms should be referred. We have already mentioned that Hooker's "Students' Flora" has been followed mainly in the style of arranging the matter, and this no doubt is an improvement in some respects on the Colonial Floras; but the absence of keys to the species of each genus, in our opinion, is not compensated for by the change. In the "Students' Flora" the synonyms are given in italics, and readily catch the eye; but in the "Flora of India" they are printed in the same type as the

descriptions, and are difficult to find, especially as one is so unaccustomed to this method. Under each genus and species the geographical area is given, and in most cases pretty fully; but most of the numerous discoveries in tropical Australia since the publication of the "Genera Plantarum" have been overlooked: we allude to those already published in the "Flora Australiensis." Other little slips of this sort occur. For instance, there is a species of *Berberis* in Abyssinia.

Dr. Hooker has contributed largely to this volume, and the following botanists have assisted:—Dr. M. T. Masters, *Malvaceæ*, &c.; Mr. W. P. Hiern, *Sapindaceæ*, &c.; Prof. W. T. T. Dyer, *Dipterocarpeæ*, &c.; Prof. Lawson, *Ampelideæ*, &c.; Mr. A. W. Bennett, *Polygaleæ*; Dr. Anderson, *Guttiferæ*; and Dr. T. Thomson and Mr. M. P. Edgeworth were also associated with Dr. Hooker in the elaboration of certain orders. A comparison of the work of the different contributors brings out the defects of some rather strongly, but it would obviously be unfair to single them out, because they have not done quite so well as the best.

This is a good solid instalment towards a portable flora of India; and with so numerous a staff of botanists, well qualified for the task, we may confidently hope that the work will proceed with tolerable rapidity. True, the first part of this volume appeared in 1872, but we anticipate a better rate of progress for future volumes.

OUR BOOK SHELF

Proceedings of the London Mathematical Society. Vol. V. 150 pp. (London: Hodgson, Gough Square, 1875.)

FORMER volumes of these Proceedings have embraced the Transactions of two and even of three sessions; this contains the Transactions of one session only; hence the smallness of the volume. The longest paper in it is a valuable geometrical memoir, by Dr. Hirst, "On the correlation of two planes." When the points and right lines of two planes are so associated that to each point in one of the planes and to each line passing through that point, respectively correspond, in the other plane, *one* line and *one* point in that line, then a correlation is said to be established between the two planes. The author indicates in a note how his results are also all applicable to the case of two homographic planes.

Prof. Cayley contributes papers on Steiner's Surface and on certain constructions for bicircular quartics. Lord Rayleigh has a note "On the numerical calculation of the roots of fluctuating functions." Mr. J. W. L. Glaisher writes "On the transformation of continued products into continued fractions." Mr. C. J. Monro has a note "On the inversion of Bernoulli's theorem in probabilities." Mr. Samuel Roberts also contributes a note "On the expression of the length of the arc of a Cartesian by elliptic functions," and "The parallel surfaces of developables and curves of double curvature;" Mr. Spottiswoode has a paper "On the contact of quartics with other surfaces;" and Mr. H. M. Taylor "On inversion with special reference to the inversion of an anchor-ring or torus." Interesting papers of a more elementary character are contributed by Mr. J. Griffiths "On the Cartesian equation of the circle which cuts three given circles at given angles," and "On a remarkable relation between the difference of two Fagnanian arcs of an ellipse of eccentricity e, and that of two corresponding arcs of a hyperbola of eccentricity $\frac{1}{e}$;" and by Prof. Wolstenholme "On another system of Poristic Equations."

So far we have cited those memoirs only which treat of pure mathematics. There are, besides, papers by Mr. Röhrs, "On spherical and cylindric motion in viscous fluid;" by Mr. Routh, "On stability of a dynamical system with two independent motions," and "On small oscillations to any degree of approximation;" by Prof. Clifford, "On graphic representation of the harmonic components of a periodic motion;" by Prof. Crofton, "A method of treating the kinematical question of the most general displacement of a solid in space;" by Mr. Merrifield, "On the determination of the form of the dome of uniform stress."

Here is, as usual, sufficient variety for differing tastes dished up by the most advanced mathematicians in this country; other names also occur as contributories of communications, though their communications do not appear in this volume, notably those of Professors Sylvester, H. J. S. Smith, and J. Clerk-Maxwell. Further, a communication by Mr. A. J. Ellis, we are informed, took the shape of a separate pamphlet, entitled "Algebra identified with Geometry." This pamphlet arose out of Mr. Ellis's connection with the Association for the Improvement of Geometrical Teaching, and copies were kindly presented by him to the members of the two societies. It is procurable at the above-named publishers of the Mathematical Society's Proceedings.

Fiji: our New Province in the South Seas. By J. H. De Ricci, F.R.G.S. With two Maps. (London: Stanford, 1875.)

MR. DE RICCI'S book has the appearance of having been put together hastily, to catch the mild and short-lived excitement connected with the annexation of Fiji. A large proportion of it consists of extracts from other works thrown together without much attempt at systematic arrangement; the result is a somewhat undigested mass of facts and figures about Fiji. Still, the book does contain a great deal of useful and interesting information, and will give its readers a very fair idea of the history and the physical and social condition of our most recent annexation. The information given may be regarded as trustworthy, as it is taken from the works of Wilkes and Seemann, and from various official documents. Appended are lists of the native names of timber-trees and of the fauna; but very much more valuable is the long systematic list of all the Fijian plants at present known, compiled partly from previous writers and partly from the author's own observations. The two maps add to the value of the work—one of the Fiji Archipelago, and the other showing the position of the colony in reference to America, Asia, and Australia.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Geology in America

I AM somewhat chagrined to find that I appear to you (vol. xi. p. 381) to say that the Geological Survey of Great Britain is especially to blame for the diminution of interest in geology in the country that has done the most for its advancement. My remarks were taken down by a reporter, and I have not seen them in print. The point I sought to make was to the effect that in all matters relating to geology, Massachusetts could not do better than to follow the lead of the British Survey. The only question to be considered was whether it was not open to criticism from an educational point of view. On this matter I expressed no individual opinion, but only restated doubts that I had heard expressed by more than one of your own masters in the science. I feel that geological science owes so much to your noble Survey, that none of its students should subject it to hasty criticism. If it is to have its methods questioned, it should be done by some one far better acquainted with its ways than any

person from another country is likely to be. It seems to me, however, that the diminution in the number of geologists, compared with the students of other sciences, if not in absolute number, is clear on simple inspection of the field. It is true not only of Great Britain, but of France and America as well. Of mining engineers there is, I believe, a great plenty; but of men who are trained in field work, who can be trusted to unravel a set of rocks, or who care for the science as a science, and not as a means of winning a living, there are far too few.

A year ago I had to organise a geological survey in the State of Kentucky. I needed three topographers and three assistant geologists who could stand alone. I picked my topographers from over a hundred competent applicants; I should have searched in vain for months for two of my geologists, had it not been that the suspension of the Missouri Survey gave me trained men. But for this I should have been driven to Germany, that inexhaustible reservoir of trained men, for my helpers. In our schools it is still worse: geology is taught in the air, not on the earth. The student never gets into the field for practical work, and the science remains for him a thing of names and shadows. With the hope of doing something to remedy these evils, there is to be a Summer School of Geology, intended for teachers of geology and those who propose to make special workers in the science, taught in connection with the work of the Kentucky Geological Survey; it will be, in fact, though taught in Kentucky for the present, the Harvard Summer Term in Geology, all the instructors in that department from this University taking a part in its work. Eight or more of the assistants of the Kentucky Survey will also be employed as instructors. Already over one hundred persons have applied for admission to the school, but the number will be limited to thirty: this list now includes twenty-five teachers of schools of academic grade, and five graduates of colleges who propose to become geologists. As the school will be placed in a camp, it will be possible, if it succeeds, to establish it in a new region each year, so that teachers attending for, say, three years in succession, may get a fair notion of our rocks, and, what is better, learn how to do field work. I believe that the novelty of the life, the freedom and fresh air, will make it possible for teachers to use their vacation time in study without damage. I am not without hope that in this way teachers may be trained to their work, and beginners provided with that practical introduction to geology which it is now so hard to obtain. N. S. SHALER

Harvard University, April 18

[We append the programme of the Summer School of Geology referred to by Prof. Shaler, in the hope that something similar may be inaugurated here.]

HARVARD UNIVERSITY.

Summer Instruction in Geology, 1875

In order to furnish an opportunity for teachers in natural science and special students in Geology to become acquainted with the methods of practical work in that science, a Summer School of Geology will be established, during the months of July and August, at a camp near Cumberland Gap, in the State of Kentucky. This place has been chosen on account of the eminent advantages it offers for the study of a great section of the American Palæozoic rocks, and of the structure of the Appalachian Mountains, and on account of the co-operation of the Kentucky Geological Survey which is promised in a letter from the Governor of that State to the President of the University. It is also a very healthy region.

The special object of this school will be to teach students to observe, but instruction will be provided in Physical Geology, Historical Geology and Palæontology, Chemical Geology, and Topographical Engineering, as far as these subjects are connected with geological work. The instruction will be necessarily incomplete, and will be expressly directed to the elucidation of the problems furnished by the area to be explored. The co-operation of six well-qualified instructors has already been secured, and a number of other able geologists have promised their presence and their aid in teaching. Some instruction in the zoology and botany of the neighbouring region will probably be given to those who desire to receive it. Certificates of attendance will be given at the end of the time. The number of students will be limited to thirty, and men only will be accepted. No previous knowledge of the science is required, but only graduates of colleges, teachers, or other persons who can give evidence of maturity and some training can be admitted.

Persons wishing to join the school should at once address J. W. Harris, Secretary of Harvard College, Cambridge, Mass. Before their enrolment they will be required to pay the fee of fifty dollars for tuition, use of tents and camp equipage, and transportation about camp. In case anyone is prevented from joining the school by illness this fee will be remitted, provided the notice thereof is given before June 15. They will also be required to pay weekly in advance the estimate for subsistence and camp servants (which is not expected to exceed three dollars per person).

Persons joining the school from the west will report themselves on June 24 and June 30, at the terminal station on the Lebanon Branch of the Louisville and Nashville Railroad. Those joining from the east will be met at a station hereafter to be designated on the East Tennessee Railroad, on June 26 or July 1. Persons unable to join on these days should notify the chief of camp, Mr. John R. Proctor, Lexington, Ky., who will arrange for their transportation to camp.

All students are expected to provide themselves with the following articles:—Two blankets, a pocket magnifying-glass, a pocket compass; Dana's "Manual of Geology," revised edition (1874), and Lyell's "Principles of Geology." Suitable notebooks will be provided at cost. Students should also provide themselves with two suits of old clothes, flannel shirts, and stout boots. The total amount of baggage should not exceed seventy-five pounds for each person. An effort will be made to secure a reduction of fares on the railroads leading to the camp.

The Attraction and Repulsion caused by the Radiation of Heat

WILL you allow me to say a few words in reference to the report of Mr. Crookes's paper which appeared in NATURE, vol. xi. p. 494. Apparently Mr. Crookes does not understand the nature of the forces which I have shown to result from the communication of heat between a gas and a surface; otherwise he would not bring forward as conclusive against the supposition that the phenomena which he has discovered are due to these forces, experiments which show entirely the other way. As I have previously explained, it follows as a direct result of the kinetic theory of gas, that if such forces as I have supposed exist for a certain tension of the gas surrounding the surface, they will not be diminished by diminishing the tension of the gas; and consequently no amount of pumping would destroy such forces where they once existed. Whereas the smaller the tension of the gas the freer the surface will be to move, and the less its motion would be opposed by convection currents; hence, on the supposition that the motion is due to these forces, the only effect of improving the vacuum would be to intensify the action. And this being the case, it is clear that Mr. Crookes's experiments, in which he finds that the action still remains in the most perfect vacuum which he has obtained, tend to support and not to upset my conclusion that the actions are due to these forces. The fact that Mr. Crookes finds it impossible to conceive this only shows, as I have said, that he does not comprehend the nature of the forces; for it certainly presents no greater difficulty than the fact that the velocity of sound is independent of the tension of the gas through which it is transmitted.

Mr. Crookes still appears to think that I attribute these forces solely to the presence of condensable vapour. It is true that the title of my first paper might have led him into this error had he read no further; but both in that paper and in a letter to the *Philosophical Magazine* for November 1874 it is clearly shown that this is not the case.

I am in hopes that ere long we may hear something on this subject from Prof. Maxwell, who probably knows more about the kinetic theory of gases than anyone else. If I am right, these experiments afford a direct proof of the truth of this theory; and as far as I know, this is the only direct proof that has ever been obtained. I do not mean to say that this is the most conclusive proof, but the most direct, or, to quote a remark of Dr. Balfour Stewart, "These experiments stand in much the same relation to the kinetic theory of gases that Foucault's pendulum occupied with regard to the rotation of the earth." No one can admire more than I do the experimental skill with which Mr. Crookes has brought the phenomena to light; nor can I see, should it turn out as I maintain, that they have led to the discovery of a law of nature, that this will detract from their importance, even if they lose somewhat in general interest from the breaking up of the halo of mystery with which they have hitherto been surrounded. OSBORNE REYNOLDS

Owens College, Manchester

The *Rôle* of Feet in the Struggle for Existence

MAY not the "set" of the feet in various races of men have played a not unimportant part in the struggle for existence? In thinking over the subject the following points have occurred to me, and perhaps some of your readers may be able to throw some further light on the question.

In the case of the North American Indian, for example, except that he wears soft mocassins instead of stiff boots, he is less in a state of nature as regards his feet than we are. For we, and all the Teutonic tribes for countless generations, have paid little regard to our feet except as instruments of unconscious progression or as pedestals on which to stand firm. The North American Indian, on the contrary, is obliged by his habits of life, and has been obliged for hundreds, perhaps thousands of years, to direct his particular attention in no small degree to the position of his feet. For in hunting it is of the greatest importance that he shall not tread on any rotten stick which may snap with a loud noise and alarm the game of which he is in pursuit. On the war track it is of equal importance that he shall deceive his enemies as to the number of his party, and so each man carefully steps in the footprint of the warrior who had preceded him. This, I should think, would be decidedly easier if the foot were kept pointing straight fore and aft than if it were held obliquely. This may be more evident from the three rough outlines I have drawn of footprints in each position, in which I have made the difference in the length of the stride much the same. Indeed, the difference is greater in the fore and aft one, and yet the impression made by the three footprints will not be so large as when the foot is oblique. In walking in snow-shoes, too, the feet must be held as nearly as possible parallel, as otherwise the shoes are apt to catch in each other and trip their wearer up. It seems quite possible that long-continued attention to the position of the feet for many generations, together with the advantage which a parallel position of the feet may have conferred in the struggle for existence, may have led to its becoming a permanent characteristic of the Red Indian; while the advantage which the outward direction of the feet may have given the old Saxon, by affording a firmer support in a hand-to-hand struggle, may have led to its permanence in the successors of those who possessed this peculiarity, and by its means enabled them to overcome their opponents.

I cannot be quite sure about the ancient Egyptians. If I remember rightly, the Farnese Hercules has toes pointing considerably outwards, while Mercury generally has his feet more or less parallel. This would indicate that the Greeks associated the former position with strength and firmness, and the latter with fleetness. As fleetness will also aid the North American Indian in the struggle for existence, it is possible that its association with a parallel foot may have something to do with the peculiar formation of his ankle-joint. This, however, leads us to the question which I do not think has ever yet been taken up: In what way does the possession of a certain kind of weapon and the use of particular methods of warfare influence the conformation of the body? Have the descendants of the Teuton tribes toes which point outwards because their forefathers used clubs, axes, and targets, and have the Red Indians of the present day parallel feet because their forefathers used arrows and keen tomahawks, and trusted to agility rather than to brazen studs and thick bull-hide for escape from the blows of their adversaries? X.

Destruction of Flowers by Birds

A WELL-OBSERVED case of the destruction of primrose flowers by birds will perhaps be of interest to some of your readers.

The flowers of two plants of primrose at a short distance from a window have during the last few days been almost entirely destroyed; and this having drawn attention to the subject, they have been watched. The result is that a number of the common house-sparrows have been seen to peck off the flowers by cutting them through at the base of the tube of the corolla, so as to remove the ovarium. In some cases the flower has not been completely detached from its stalk, a ragged hole being left where the ovarium originally was placed, but the flower has never been subject to any further dismemberment. The few flowers which have been left on the plants, when chewed in the mouth, do not seem to have any sweetness about them, and one would therefore suppose that they do not contain any appreciable quantity of nectar.

The inference from these observations seems to be that the sole object of the destruction of the flowers is to obtain the ovaria. It is also to be observed that the primrose is not indigenous to this part of the country, and the only plants within a radius of at least two miles are those cultivated in gardens. The cowslip is, however, very abundant, but I have never noticed any similar destruction of it. I shall, now the cowslips are coming into flower, watch them with the object of finding out whether they are attacked or not.

H. GEORGE FORDHAM

Note on the Common Sole

IN looking over Mr. Buckland's last work on "British Fishes," I did not find any account of the power the Sole has of fixing itself against the glass of an aquarium by means of a sucker placed close to the mouth, on the lower side; and as I find it is one of the "things not generally known," I think it may be worth your notice, particularly as I have not remarked it at the Brighton Aquarium. I first observed the fact at the Havre Aquarium, where I pointed it out to many persons hitherto unacquainted with it, but I have been disappointed at not seeing it at Brighton during any of my visits. The only way I can account for this difference in the habits of the same fish is that the Brighton Soles being, during my visits, always in the light, lay quietly at the bottom, whereas those at Havre, being almost excluded from the light, were seen to much greater advantage, swimming about freely and attaching themselves to the glass when they came in contact with it, or sliding down to the ground. The sucker of a Sole nine inches long would be about $\frac{3}{4}$ inch by $\frac{1}{2}$ inch, placed diagonally to the long diameter of the fish, and exhibiting fine radiating lines. Though I watched other flat-fish carefully, I never could detect any attempt in them to fix themselves against the glass when they struck it, and therefore I am quite unable to explain why the Sole alone should have this power. As I make no pretension to be an ichthyologist, it is very probable that I may be telling a thrice-told tale. I must therefore leave it to your judgment to decide whether it is worth your notice in NATURE. T. OGIER WARD

Eastbourne

Colour in Goldfinches

LAST July I took a goldfinch's (*Carduelis elegans*) nest with five young birds in it out of a tree in my garden and brought them up. Four turned out to be properly marked specimens, but the fifth is almost black, only having a few red feathers on its head. I see in Bechstein's "Cage Birds" (third edition), p. 147, that "four young ones of this variety were found in the same nest." Now, why were not all my five specimens black, and what is the cause of the fifth's blackness? Can any of your readers say?

Manley, May 1 LUCIE WOODRUFFE

OUR ASTRONOMICAL COLUMN

VARIABLE STARS.—The two following stars require further examination, as affording signs of fluctuating brightness. (1) Lalande 23228–9, estimated 7th magnitude, 1795 May 8, and $5\frac{1}{2}$, 1798 March 14. It is 6·7 in Lamont (No. 1149), and in Steinheil's Chart, one of the series published by the Berlin Academy, it is only 8th mag. Neither Bessel nor Santini has observed it. (2) The star Lalande 27095, in Boötes, 7th mag., observed 1795 May 25, and missed by Olbers, 1804 March 22, during his observations of the comet of that year: it is the star which passed the centre wire at 14h. 42m. 10s. (Histoire Céleste, p. 164), and Olbers distinctly says of it "ist nicht mehr am Himmel zu finden." It was, however, observed by Bessel in his Zone 415, 1828 May 24, as a 9th magnitude; it is 9·0 in the "Durchmusterung," and is called 9·1, 1866 June 5, in the Bonn Observations, vol. vi. The positions of these stars for 1875·0 are:—

(1) R.A.	12h.	18m.	45s.	N.P.D.	100°	54′·9
(2) ,,	14	45	54	,,	52	6·3

THE BINARY STAR Σ 2107.—This undoubted binary, first measured by Struve in the year 1828, well merits attention, and it may soon be possible to gain an idea of the form of the orbit. The recent measures of Dembowski and Barclay prove the angular velocity to be still increasing, the accompanying diminution of distance requiring pretty large telescopes to be brought into requisition for satisfactory observations. Dembowski calls the principal component a 7th magnitude, bright yellow; the smaller one a 9th and dusky. This star is Herculis 197 (Bode), and its place for 1875·0 is in R.A., 16h. 46m.54s.; N.P.D., 61° 7′.

HIGH-LATITUDE PHENOMENA.—Our correspondent "H. F. C.," who writes from San Francisco, California, with regard to a statement in the recently-published narrative of the "German Arctic Expedition," that "the moon shone without setting for several days" in November, refers to a phenomenon which must necessarily occur in circumpolar latitudes. As an illustration: In lat. 82° N. and long. 60° W., near which position a part of the expedition about to leave our shores is expected to winter, the moon in December next will rise on the 8th, and will not set until the 18th, attaining her greatest altitude above the horizon at meridian passage on the 13th. The sun during this interval is, of course, invisible in lat. 82° N., but there is continuous moonlight for between nine and ten days, and similarly for other months during the Arctic winter.

THE SOLAR ECLIPSE, 1876, MARCH 25.—This eclipse will be a very similar one to that of March 1858, which created so much interest in its passage across this country: it will be annular, but in those parts of the track of central line, where the augmentation of the moon's geocentric semi-diameter is greatest, the eclipse, though still annular (as in England in 1858), approaches very near a total one. Vancouver Island is situate in this track, which runs about centrally over it, as the following points will show:—

Longitude 127° 6′ W.	Latitude, 48° 42′ N.
" 126 4	" 49 30
" 125 51	" 49 40
" 125 15	" 50 6
" 122 46	" 51 50

A direct calculation for the third of the above points, in Vancouver Island, gives for the duration of the *annulus* only 7·5 seconds, the middle at 0h. 25m. 29s. local mean time with the sun at an altitude of 44°: the apparent semi-diameter of the moon is 1″·5 less than that of the sun. The central line subsequently traverses the Lesser Slave Lake and Lake Athabasca, with slightly longer duration of *annulus*. The eclipse will be visible in its partial phase in the position of the winter quarters at which the British Arctic Expedition aims.

THE MINOR PLANET "LYDIA."—M. Leverrier's *Bulletin International* of April 29 contained a telegraphic notice of the discovery of a supposed new member of the minor planet group, at the Observatory of Toulouse, by M. Perrotin, on the same morning, which in the following *Bulletin* is recognised as No. 110, Lydia, detected by M. Borrelly at Marseilles on April 19, 1870; the ephemeris (*Berliner Jahrbuch*) being much in error. The elements of No. 110, calculated by Dr. Oppenheim of Königsberg, and brought up with perturbations to 1874 (*Astron. Nach.*, No. 1,971), give a position for April 28, differing considerably from that assigned by the observation at Toulouse; but if we apply a correction to the mean anomaly of +1° 21′ 57″, the observed and computed longitudes agree, and the latitudes differ only one minute, and the diurnal motions also accord, so that there can be little doubt that the identification of M. Perrotin's object with No. 110 is correct. With the above correction the mean anomaly, April 28·5 Greenwich mean time, is 262° 8′ 27″, and thus with the other elements given by Dr. Oppenheim we have the following positions, which will be pretty near the true ones. At 12h. Greenwich mean time:—

	R.A. h. m. s.	N.P.D. ° ′	Log. distance.
May 3	15 4 17	105 29·5	0·2498
" 5	2 27	" 25·8	
" 7	15 0 36	" 22·2	0·2481
" 9	14 58 45	" 18·5	
" 11	" 56 54	" 14·9	0·2476
" 13	" 55 4	" 11·3	
" 15	" 53 15	" 7·8	0·2482
" 17	" 51 28	" 4·4

LECTURES AT THE ZOOLOGICAL GARDENS*

Mr. J. W. Clarke on Sea Lions and Seals

II.

THE Sea Lion that is best known is the Northern Sea Bear (*O. ursina*), which is almost entirely confined to the Pribylov Islands. These islands were discovered in 1787 by a Russian sailor of that name. The slaughter of the animals is under the regulations of the United States Government. There are two islands, that of St. Paul and that of St. George, and the number of seals that have been calculated to exist in a given year upon one of them—namely, 1,152,000—will give a good notion of the multitudes of these animals to be met with at one of their favourite haunts. There is about half that number on St. George, making nearly 2,000,000 on the two islands. Out of this vast number, 100,000 are annually killed, principally young males. In South Shetland the "take" of fur seals was 320,000 in 1821 and 1822, and as all that arrived were killed, the speedy extinction of the colony was the result. The same happened in New Zealand.

A full-grown male *Otaria ursina* is between seven and eight feet long, the female not being more than four feet. The males reach their maximum size at about the sixth year, the females at the fourth. The hairy coat consists of an outer covering of long, flattened, coarse hair, beneath which is a dense coating of long, fine, silky fur.

The next species is Steller's Sea Lion (*O. stelleri*), named in honour of its discoverer. It is much larger than the other species, the males being as much as sixteen feet long. The ears are short and pointed, much broader than those of the Fur Seal. It is found on the island of St. Paul, extending down the coasts of Kamschatka and California. At San Francisco it inhabits an island in the harbour where Mr. Woodford has built a large hotel, to which parties resort to dine and look at the Sea Lions play. The under-fur of this species is so short as to be useless for clothing purposes.

There is another Otaria on the Californian coast, found in Japan also. It was first described by Schlegel from specimens collected by Siebold. It has been named *O. gilliespii*, but it would be far better to adopt the name since suggested by its original describer, and call it *O. japonica*. It is much smaller than the species named after Steller, and the skull presents an exceptionally large crest.

The next species to be mentioned is the one which extends round South America, from Peru to the River Plate—*Otaria jubata*—of which a specimen is living in the Gardens, having been obtained by its keeper, François Lecomte, from the Falkland Islands, when a mere pup. A full-grown male may reach nine feet in length, the females being much smaller. The fur is of no use for sealskin, as the undercoat is very scanty. The male has a mane, and is therefore called "Lion."

Inhabiting precisely the same localities, round Cape Horn and the Falkland Islands, is the Fur Seal of commerce—*Otaria falklandica*. It is much smaller than the

* Continued from vol. xi. p. 514.

other species, a full-grown male being hardly more than four feet long. It is probable that it is identical with one of the New Zealand Fur Seals, described by Dr. Gray as *Otaria cinerea*. If this should turn out to be the case, it will have a wider range than any of the others of the group.

There is certainly another species of Sea Lion on the coast of New Zealand, called Hooker's Sea Bear—*Otaria hookeri*. Its only certain habitat is the Aucklands. It is a large species, the males about six feet long, the females proportionately smaller. Though these New Zealand coasts and islands, together with the coasts of the mainland of Australia, have been visited and surveyed in every direction by English expeditions, no one has ever thought of preserving specimens for museums, so that we really know less about the seals of our colonies than we do about those of foreign coasts. Thus there is certainly a large species on the west coast of Australia, at the group of islands called Houtman's Abrolhos, described by Dr. Gray as *Neophoca lobata*. We are almost equally ignorant about the Sea Lions of the Cape of Good Hope. The species from that locality living in the Gardens—*Otaria pusilla*—is a very small one with an excellent fur. The Antarctic Sea Lion—*Otaria antarctica* (Gray)—is also from the Cape. This completes the number of species of Otarias, which may be thus tabulated :—

OTARIA

Pusilla *Antarctica*	from South Africa and the adjacent islands.
Jubata *Falklandica*	from Cape Horn and the adjacent islands.
Japonica *Stelleri* *Ursina*	from the North Pacific.
Hookeri *Lobata*	from Australia and New Zealand.

In some respects intermediate between the Sea Lions and true Seals, is the Walrus, an animal with the head flattened in front, the upper lips with long stiff whiskers, the two enormous tusks, the short bull-like neck, and the vast carcase. Stuffed specimens err in being too distended and smooth, all the natural wrinkles being removed. The hair is thin and short. The attitude resembles in the main that of the Sea Bear, as do the limbs, the thumb being the longest digit, and the hind feet directed forward. There are no external ears, but a fold of skin above the auditory opening. The eyes, destitute of lashes, are deeply set. The tusks, developed in the female as well as in the male, never exceed twenty-six inches in length, including the imbedded root of six inches. The creature is omnivorous. It is becoming very scarce in its favourite haunts, on account of the indiscriminate way in which it is slaughtered. Upwards of 1,000 are still taken annually in the neighbourhood of Spitzbergen. Formerly it was found at Bear Island and on the coast of Finmark. It is still found on the east coast of Greenland, on the west shore of Davis' Straits, about Pond's, Scott's, and Howe Bays. In 1775 they resorted, to the number of over 7,000 a year, to the Magdalen Islands, at the mouth of the St. Lawrence, and the English once had a fishery at Cape Breton. It can be mentioned only as a straggler to our coasts.

Every part of the animal is of value—the tusks, the hide, and the flesh. The word *Walrus* means "Whale Horse," *Ross* being the Danish for a steed. *Morse* is Russian. The Greenlanders call it *Awŭk*, a name derived, it is said, from the cry of the young animal.

Seals are in a state of far less confusion than Sea Lions. The species are numerous, Dr. Gray recognising fourteen species and thirteen genera. As a basis for classification, the number of incisor teeth, together with the shape of the hands, leads to a very natural arrangement of the family. Following this, we find that four incisors above and four below unite the four Seals of the Southern Ocean with the Mediterranean Seal. The six northern species, again, have all six incisors above, and four below, their hands being like those of the "Bearded" and "Common" Seals. Lastly, four incisors above and two below separate off those very remarkable forms, the "Bladder Seal" of the north and the mighty "Sea Elephant" of the south, which have the further point in common of a remarkable development of the nasal passages. The Sea Leopard—or Leopards, if there are really two—together with the Crab-eating Seal, which ought most probably to be united in the same genus with them, inhabit the Antarctic Ocean. In the last-named species the molar teeth are remarkably modified.

The fourth Antarctic Seal is that called *Ommatophoca rossi*—Ross's Large-eyed Seal, known only from specimens procured from Sir J. Ross's Antarctic Expedition. The next species we come to is the Monk Seal (*Monachus albiventer*), which inhabits the Mediterranean and the Island of Madeira.

Of the "Hooded Seal," or "Bladder Nose," till a few days ago a fine male specimen was living in the Society's Gardens. The length attained ranges between seven and twelve feet. Though a true seal, it has the power of using the fore-feet to walk on land to a certain degree. The nose is broad and flat, and in the male the upper wall of the nostril is so loose that it can be blown up at will into a hood. The use of this curious appendage is not known. Its habits are migratory. It is found in South Greenland, rarely in Iceland and Norway, never now at Spitzbergen. The nearest ally to this seal is the "Sea Elephant," described by Anson in 1742, from Juan Fernandez. It has been recorded to be thirty feet long. The nostrils of the male are prolonged into the remarkable appendage which has been the origin of its name, "Proboscis Seal," the tubular proboscis being, when inflated, a foot in length.

Round the English coast there are two species of seals that are tolerably common, the Common Seal (*Phoca vitulina*) and the Great Grey Seal (*Phoca gryphus*). The former frequents both sides of the North Atlantic, Spitzbergen, Greenland, and Davis' Straits. The latter species is far rarer in this country. It is not found in Polar waters nor in the Mediterranean Sea, where the former exists. Further north we come to three other seals, the Bearded Seal (*P. barbata*), the Greenland Seal (*P. grœnlandica*), and the Ringed Seal (*P. hispida*); the two latter sometimes appear on our coasts as stragglers.

The lecturer concluded by remarking on the necessity for some international agreement to prevent the destructive effects of the short-sighted policy now adopted in seal-hunting.

(*To be continued.*)

ON LIGHTNING FIGURES

THE letter headed "Struck by Lightning," and signed "D. Pidgeon," contained in NATURE, vol. xi. p. 405, is valuable, and the more so because it is unaccompanied by any theory. Formerly, when ramified marks appeared on the persons of men or animals, they were always referred to some near or distant tree, of which the marks formed "an exact portrait." Thus, in the *Times* of September 10, 1866, is an account of a boy who had taken refuge under a tree during a thunderstorm, having been struck by lightning, and on his body was found "a perfect image of the tree, the fibres, leaves, and branches being represented with photographic accuracy."

In a paper read by me before the British Association at Manchester in 1861, I attempted to show that such ramified figures are not derived from any tree whatever, but represent the fiery hand of the lightning itself. Very instructive tree-like figures may be produced on sheets of crown glass by passing over them the contents of a Leyden jar. For this purpose the plates (those I used were

four inches square) should be put into a strong solution of soap, and wiped dry with a duster. If a plate be then held by the corner against the knob of a small charged jar, and, with one knob of the discharging rod resting against the outer coating, the other be brought up to the knob of the jar with the glass between, the spark will pass over the surface of the pane, turn over its edge, and thus arrive at the knob of the rod. Nothing is visible on the plate until it is breathed on, and then the condensed breath settles in the form of minute dew on those parts of the soapy film that have not been burnt off by the electricity, while on the lines that have been burnt off or made chemically clean the moisture condenses in watery lines, bringing out the trunk, branches, and minute spray of the dendritic figure in a very perfect manner. In the discussion that followed the reading of my paper, the president of the section remarked that the figures exhibited would pass for trees all over the world. The discharge sometimes exhibits bifurcations and even trifurcations. The main trunk is evidently a hollow tube, as in the vitrified masses known as fulgurites, where lightning

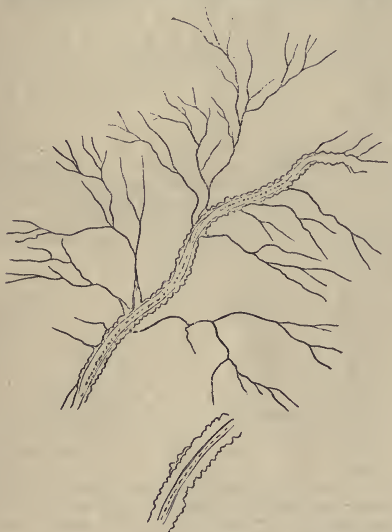

FIG. 1.—Breath Figure of Electric Discharge (also called *Roric Figure*, from *Ros-roris*, "dew.")

ploughs through a sandy soil. Should the plate be too thick, the main discharge may not pass, in which case the plate represents spray only. Hence I infer that the spray precedes the discharge and acts as a feeler for the line of least resistance. Indeed, it is an old observation of sailors, that before the ship was struck everyone on board felt as if cobwebs were being drawn over his face.

The accompanying (Fig. 1) is one of the figures produced as above described, the separate figure being an enlarged portion of the stem or trunk which represents the main discharge. Other examples may be found in the "English Cyclopædia" (Arts and Sciences division), article "Breath Figures," and in the *Edinburgh New Philosophical Journal* for October 1861.

After the reading of my paper I was anxious to see some examples that had been undoubtedly produced by lightning of these ramified figures. I was gratified by the receipt of a letter from Dr. Pooley, of Weston-super-Mare, informing me that he had actually seen a tree struck by lightning, that the inner surfaces of the detached bark contained ramified figures such as I had described, and that he had sent specimens to Dr. Faraday. I accordingly applied for permission to examine them. The figures on the bark had become very faint, but the following engraving (Fig. 2) represents their character.

In the *Lancet* of July 30, 1864, Dr. D. Mackintosh describes a case in which a straw stack was struck by lightning and set on fire, while a man who had sought its shelter was killed, and two boys injured. One of the boys, aged ten, said he felt "dizzy all over;" his legs would not carry him, and he felt pain in the lower part of the abdomen. On taking off his clothes a peculiar sulphurous singed odour was perpectible, and also several irregular but distinct red streaks, of about a finger's breadth, running obliquely downwards and inwards on either side of the chest to a middle line in front of the

FIG. 2.—Three Portions of the Inner Surface of the Bark.

abdomen, whence they converged; from this point they diverged again till they were lost in the perineum. The streaks were of a brighter red on the more vascular parts of the body; they disappeared in about four days, and the lad recovered.

In the second case, that of a boy aged eleven, "the figures on either hip were so exceedingly alike and so striking, that an observer could not but be impressed with the idea that they were formed in obedience to some prevailing law."

In the third case, that of a man of forty-six, the discharge passed through the head, and seems to have produced instant death.

The phenomena in the case of the two boys agree very well with those described in Mr. Pidgeon's letter.

But there are various other figures produced by lightning sufficiently numerous to have led M. Baudin, in his

"Treatise on Medical Geography," to apply to them the term *Keraunography* (to write with thunder). Mr. Poey, in 1861, published a small volume in which twenty-four illustrative cases are cited. The author starts with the popular notion that the dendritic figures referred to are derived from some near or distant tree, and then proceeds to account for them by means of a photo-electric action in which the surface of the animal is the sensitive plate; the tree, &c., the object; and the lightning the force that impresses it.

But in connection with our subject are other facts, startling, it is true, but recurring from time to time in different parts of the world, and reported by sailors and others, who possess the invaluable art of recording their observations without attempting to explain them. The desire of explaining everything often amounts to a kind of rabies, when the sane course seems to be to wait; for if a reasonable theory is impossible, an unreasonable one is ridiculous. Nevertheless, some observers, if they cannot explain a fact, deny its truth; and yet such facts may exist in nature, and only wait the progress of discovery, when in due time they are gathered in under the sickle of the appointed reaper. Three such facts are the following:—

1. In September 1825, the brig *Il Buon Servo*, anchored in the Bay of Armiro, was struck by lightning, and a sailor who was sitting at the foot of the mizenmast was killed. Marks were found on his back, extending from the neck to the loins, including the impression of a horse-shoe, perfectly distinct, and of the same size as the one that was fixed to the mast.

2. In another case that occurred at Zante, the number 44 in metal was attached to the fixed rigging between the mast and the cot of one of the sailors. The mast was struck and the sailor killed. On his left breast was found the number 44, well formed and perfectly identical with that on the rigging. The sailors agreed that the number did not exist on the body before the man was struck.

3. M. José Maria Dau, of Havannah, states that in 1828, in the province of Candelaria, in the island of Cuba, a young man was struck by lightning, and on his neck was found the image "d'un fer à cheval qui avait été cloué à peu de distance contre une fenêtre."

Unexpected light was thrown upon such cases by Mr. C. F. Varley (Proc. Roy. Soc., Jan. 12, 1871), in following up an accidental observation during the working of a Holtz electrical machine, the poles of which were furnished with brass balls about an inch in diameter. Noticing some specks on the ball of the positive pole, Mr. Varley tried to wipe them off with a silk handkerchief, but in vain. He then examined the negative pole, and discovered a minute speck corresponding to the spots on the positive pole. This pole sometimes exhibits a glow, and if in this state three or four bits of wax, or even a drop or two of water, be placed on the negative pole, corresponding non-luminous spots appear on the positive pole. Hence it is evident that lines of force exist between the two poles, by means of which we may telegraph through the air from the negative to the positive pole. And in explanation of the above cases in which the lightning-burn on the skin is of the same shape as the object from which the discharge proceeded, all that is necessary is that the object struck be + to the horse-shoe, brass number, &c., the discharge being a negative one.

C. TOMLINSON

INAUGURATION OF THE ZOOLOGICAL STATION OF NAPLES

AFTER the first working year a formal inauguration of this new institution took place on April 11. Dr. Dohrn had invited the Italian Minister of Public Instruction, Signor Borghi, and the German Ambassador at Rome, Herr von Kendell, to be present as representatives of the two countries which had most assisted in completing the new establishment, the one granting the locality, whilst the other paid a subvention of 3,000*l.* towards the expenses of the construction. Unfortunately both gentlemen were at the last moment prevented from being present, but sent two letters stating their great sympathy and the sympathy of the two Governments which they represent, for the Zoological Station.

The inauguration solemnity consisted chiefly in an inaugural address read by Dr. Dohrn himself to an audience of distinguished gentlemen, and a short answer given by Signor Paureri, the well-known Professor of Anatomy of the Naples University.

Before giving an abstract of the address, it may be permitted to say a few words about the life and work of the Zoological Station during the first year of its existence.

The following naturalists have made use of its laboratories:—From *England:* Mr. Balfour, Mr. Dew Smith, Mr. Marshall, from Cambridge; Mr. E. Ray Lankester, from Oxford. From *Holland:* Mr. Hubrecht (Leyden), Dr. Hoek (Haag), Prof. Hoffmann (Leyden), Dr. Hoorst (Utrecht), Prof. Van Ankum (Groningen). From *Germany:* Prof. Waldeyer (Strassburg), Prof. Wilh. Müller (Jena), Dr. Korsmann (Heidelberg), Prof. Hesslöhl (Constanz), Prof. Greeff (Marburg), Profs. Kollmann and Ranke (Munich), Dr. Steiner (Halle), Prof. Oscar Schmidt (Strassburg), Prof. Langer Lans (Freiburg), Dr. v. Thering (Göttingen), Dr. Götte and Dr. Lorent (Strassburg), Dr. Vetter (Dresden), Prof. Selenka (Erlangen). From *Austria:* Prof. Claus (Vienna) with two students of the Vienna University. From *Russia:* Prof. Salensky (Kazan), Dr. Rajewsky (Moscow), Dr. Bobretzky (Kiew), Dr. Ulianin (Moskau), Dr. Rosenberg (Dorpat), Cand. Isnoskoff (Kazan). From *Italy:* Dr. Cavanna (Florence), Dr. Fanzago (Padua), Dr. Zingone (Naples).

Some of these naturalists have been working a whole year in the Zoological Station; some have come back a second time; the greater number have only stayed the winter, especially from February till May, a period when the Station is likely to be visited more frequently than at any other.

If one compares the number of naturalists coming to Naples in former years to study Marine Zoology with the number of those who are named above, it is at once obvious how great an effect the Zoological Station has had on the increase. Formerly from three to five zoologists used to come during the year to Naples, often even less, or none. From Easter 1874 till Easter 1875, there were thirty-six naturalists, and during March and April of this year alone there have been working contemporaneously in the Zoological Station eighteen zoologists.

This shows how considerable in a quantitative point of view the increase of scientific work done at Naples has become. It is besides obvious that the arrangements in the Zoological Station—the great Aquarium providing almost natural conditions of life to the animals, the daily supply of fresh material, the facility offered by the library for consulting the literature, and the personal intercourse among so many scientific men,—must have also a favourable influence on the quality of the work, by enabling each of the naturalists to concentrate his energy solely on the scientific difficulties of his pursuit, not having at all to deal with any of the tiresome, very trying, and for a single man often almost insurmountable obstacles of a more practical character which are in the way of these studies.

Besides, one must not forget that the Zoological Station is still in its infancy, and has grown to its present state of working order in the midst of difficulties of every kind and character. Granted a greater experience in the line of its actions, especially a greater knowledge of the sea and its localities, currents, temperatures, and other conditions affecting the life and habitat of

the animals; granted, further, an increased income to allow a more liberal endowment of its different parts, viz., library, collection, laboratories, and also an increase in its leading and scientific staff; granted, finally, new donations and subventions like those of the English naturalists and of the German Government, and we may be pretty sure that the Zoological Station at Naples will in future be a quite indispensable and very powerful instrument for scientific research.

At present the following Governments and Universities have entered upon contracts with the Zoological Station for one or two tables:—Prussia, Italy, Russia, Austria, each for two tables; Bavaria, Saxony, Baden, Mecklenburg, Holland, and the Universities of Cambridge and Strassburg, each for one table. Negotiations have been entered upon with Würtemberg and Hesse-Darmstadt. Accommodation for twenty-four naturalists will be ready for next winter, and it is hoped to augment the daily arriving quantity of marine animals for investigation by help of a small steam launch, which will be always out on fishing expeditions, weather permitting.

All this together shows a regularly working institution, which, we believe, deserves the full attention of scientific men as a new element, or, to use an expression applied to it once by Prof. Owen, a new dynamic in science.

The following is an abstract of Dr. Dohrn's inaugural address:—

Dr. Dohrn began by referring to the success which has hitherto attended the Naples establishment, to the Andersonian School of Natural History in America, and to the Zoological Station which the Austrian Government proposes to establish at Trieste. He then proceeded to show what may in time be expected from the institution; in what its duties principally consist.

The original purposes of the undertaking was to facilitate the labours of the zoologists who come to Naples from all parts of Europe to study the marine animals of the Bay. For this purpose it is of course necessary to enter into relations with the fishermen in the Bay, in order to obtain the needed supply of fish; but this method is so far from satisfactory that Dr. Dohrn, as soon as the state of funds permits, is resolved to obtain a small steamer, properly fitted up; with such assistance only can the purposes of the institution be satisfactorily carried out.

Dr. Dohrn then referred to the library of the Station, which he is exceedingly anxious to make as complete as possible, and hopes that authors, publishers, and academies will continue to supply the wants of the Station in this respect. He is especially anxious to obtain systematic works, the want of which has already made itself painfully felt. The institution greatly depends upon its pecuniary resources, and he hopes those who are friendly to its purpose will continue to lend it a helping hand.

The Zoological Station will continue to supply foreign universities, laboratories, museums, and private collections with marine animals, carefully preserved according to the directions of the person who orders them.

Besides thus endeavouring to further the work of others, the Station has important scientific tasks of its own. One of the chief of these is an exact determination of the fauna of the Bay. Not only for its own sake is this task one of the first duties of the Station, but it will be of great assistance in facilitating the work of the Station in other directions. It may be objected that the smallness of the means at the disposal of the Station is inadequate to the fulfilment of all these purposes. While the justice of this objection is admitted, there is at the same time no doubt that a great future is in store for Zoological Stations; for the principle on which they are founded will remain, and give rise to ever new realisations.

The decreasing importance which the study of zoology holds in the medical curriculum can hardly be avoided without inordinately lengthening the time required for such a course, medical science itself has become so subdivided and specialised. Still, those who look upon the medical profession as something more than merely a means of livelihood, will not treat zoology with indifference, but will perceive the important bearing it has on the proper understanding of many medical problems.

The importance of the principles of the Development theory on the progress of medicine are then insisted on. In the case of transmission of a hereditary tendency to certain forms of disease, the application of these principles might be made to serve a most important purpose, if thoroughly understood and carefully carried into practice. "How important must it be to ascertain the conditions of such a transmission, to discover the symptoms which, though in the present state of our knowledge they may escape observation, may in the earliest years show a morbid predisposition, and thus warn us to conduct the whole physical and moral education of the child with reference to the hidden enemy. . . . As soon as these truths have become a part of the intellectual possessions of the people, as soon as physicians and teachers bear them constantly in mind and act in accordance with them, how different will education become! For in this the highest significance of the Darwinian theory consists, that its principles embrace the moral as well as the physical nature of man, and that their critical application may bring about intellectual as well as corporal changes.

"As soon as its high practical value is established and recognised, no doubt can be entertained that the progress of zoology, the chief exponent of these laws, is an essential furtherance to the advance of morals and the reasonable adjustment of human life; and it follows that society—and the highest form of society, the State—are not only entitled, but in duty bound, to afford a free opportunity for zoological investigation, and to support it by all the means in their power."

Zoology is now so advanced and subdivided that at the various universities the professorships of Zoology should be at least doubled; no man is able adequately to teach all branches of it. Moreover, laboratories must be established at the seaside, and still more, stations in various parts of the world.

Dr. Dohrn bespoke the utmost toleration for the Darwinian theory from all classes. He hoped that the fact that he had connected the name of the Station with the development and application of the Darwinian theory would not prevent anyone from lending it his support.

"When the fundamental principles of Darwinism are once thoroughly understood, it becomes clear that it is not nearly as revolutionary as some of its disciples seem to suppose. On the contrary, it is the declared enemy of all revolutions. It takes its stand on concrete reality, and teaches, like Hegel, that the real is the reasonable. It sees in all that exists the necessary result of a long process of development, in which innumerable influences have contributed to render the present world what it is, and not something quite different from it. But it sees in the present world only the *present* world; to-morrow it will be changed. What in to-day is the effect of yesterday, must at the same time be the cause of to-morrow. Thus Darwinism is at once extremely tolerant and the prophet of a different future. If at times this should not appear to be the case, the blame is due, not to the theory, but to its advocates, who often seem not to understand the doctrines they so zealously teach, since they are enraged at an opposition which, if they understood how necessary and inevitable it is, they might with ease gradually but certainly remove."

It was shown that the Development theory is applicable to all forms of existence and to all departments of human life. If the law were carefully applied to history as well as to nature, we might hope to be able to reduce the phenomena of both to one great law of development, by

means of which we should be enabled better to understand both the past and the future, and to judge more clearly of the present.

The important bearing which the work at the Naples and similar stations had on the elucidation of this law was then pointed out. "Every fish, every crab, every Medusa is the result of a long process of development, which we have to trace, and the determination of which the Zoological Station is intended to facilitate. That is its purpose; it was for that end that I built it, and for that reason I have asked you to lend your support to my efforts."

THE "VILLE DE CALAIS" BALLOON ASCENT

PARIS, *May* 3.

WE made our ascent yesterday from La Villette gas-works at 1·25 P.M., and landed safely in a field at Creney, a small country place four miles south-east of Troyes, which is about 100 miles south-east from Paris. After having made observations during a little less than six hours, our grapnel was let down at ten minutes past seven. There were three of us in the car—M. Duruof, Mr. Marriott, an English correspondent in Paris, and myself. The maximum altitude reached was about 12,000 feet. The ascent was very gradual, and the above height was reached only at six o'clock. No sensible effect was perceived, although the temperature of the air, which on the ground was about 50° F., was no more than 26° at this altitude. We tried several experiments, with what success it remains to determine on examination of the apparatus. Some of the results, however, I am able to state here.

We had suspended to the net a number of cages containing small birds and guinea-pigs. The current of gas had a decided inclination to flow in a certain direction, and we had not ascended 6,000 feet when one of the birds was found dead by suffocation. It was the only bird exposed to the inhalation of the current of gas, and no other was injured. It was proved by a careful autopsy executed this morning by Dr. Lionville that this bird had perished by intra-osseous hæmorrhage in the cranium. The hæmorrhage had taken place on both sides, and without any lesion appearing to the exterior.

We discovered that not less than four different banks of clouds were being carried over Paris and its vicinity. Before the end of our journey the clouds had considerably diminished in thickness, and the blue sky appeared. I was able to take some thermo-solar observations with a blackened bulb thermometer *in vacuo*.

As the effect on our constitutions of our 12,000 feet trip was very trifling, I am of opinion that the experiment may be scientifically conducted gradually to an immense altitude, independently of previous catastrophes.

W. DE FONVIELLE

NOTES

As we announced some months ago (Dec. 24, vol. xi. p. 153), Prof. Huxley is to undertake the duties of Prof. Wyville Thomson's chair of Natural History in the University of Edinburgh during the present summer session. Prof. Huxley gave his introductory lecture on Monday afternoon to a large audience. He was accompanied by Principal Sir Alexander Grant, Principal Tulloch, St. Andrews, and the members of the Senatus, and was enthusiastically received. He expressed at the outset a hope that at this time next year Prof. Thomson would be among them again, full of health and vigour, laden with the spoils of the many climes through which he had travelled, and a sort of zoological Ulysses, full of wisdom for their benefit. He then took a general view of his subject, put before the class the considerations which resulted from the careful study of a single animal, the Crocodile; an animal which was worthy of attentive study, as it might be said that a knowledge of its organisation was the key to the understanding of a vast number of extinct reptiles, and the key to the organisation of birds; while it helped them to connect the higher with the lower forms of vertebrate life, and was, in part at any rate, the key to the history of past life upon the globe. There might be asked respecting this animal, as respecting every other living thing—first, what was its structure? second, what did it do? third, where was it found? and fourth, in virtue of what chain of causation had this thing come into being?—this last having only been recently recognised as one of those questions which might legitimately be put. He then proceeded to describe the organisation of the Crocodile—its morphology, physiology, and distribution; and remarked that there were few animals about the palæontological history of which they knew so much, as they could carry back its history through the tertiary and secondary epochs. The answer to the last question constituted Ætiology, or the science of the causes of the phenomena of morphology, physiology, and distribution. Here, as in all cases where they had to deal with causation, they left the region of objective fact and entered that of speculation. With their present imperfect knowledge, the only safe thing they could do in attempting to form even a conception of the cause of this extraordinary complex phenomenon was what a wise historian would do—stick by archæological facts. He pointed out that palæontological facts showed that there had been a succession of forms of that animal to the present day, the oldest being something like the Lizard.

THE Instructions prepared for the use of the officers of the Arctic Expedition in their Scientific work are now nearly complete, and all the courses of instruction, comprising the use of magnetical, astronomical, and meteorological instruments and of spectroscopes, will be concluded next week, many officers from both ships having taken part in them. We believe that the present arrangement as to date of leaving, the 29th instant, may be considered as final. We have already stated that the exploring ships are to be accompanied as far as Disco Island by the *Valorous* for the purpose of enabling them to fill up with stores and coal at the last moment. At the suggestion of the Council of the Royal Society, advantage will be taken of the presence of this ship to make observations in a little explored region, her homeward voyage being employed in carrying out such a physical and biological exploration of the southern part of Baffin's Bay and the North Atlantic between Cape Farewell and the British Isles as may serve to complete the work which is being so successfully prosecuted in other seas by the *Challenger*. Mr. J. Gwyn Jeffreys, the coadjutor of Dr. Carpenter and Prof. Wyville Thomson in the *Porcupine* expeditions, which first demonstrated the feasibility and scientific importance of this kind of exploration, has volunteered for the service, and he will take with him as his assistant Mr. P. Herbert Carpenter, who did good work when accompanying his father in the *Porcupine*, and who will especially take charge of the physical inquiries.

M. CORNU's lecture on the velocity of Light at the Royal Institution to-morrow evening is looked forward to with great interest. We believe he intends to speak in French, though his knowledge of English renders him quite competent to make use of that language if he chose. An account of the results attained by M. Cornu will be found in NATURE, vol. xi. p. 274.

HOFRATH HEINRICH SCHWABE died at Dessau on April 11; he reached a patriarchal age, having been born on Oct. 25, 1789, at Dessau. He retained his faculties to the last, although he had been compelled for many years to relinquish his favourite astronomical studies, which in 1857 had won for him the Royal Astronomical Society's Gold Medal.

CHEMISTRY in Germany and in Austria has to deplore two severe losses. On the 15th of April died Prof. von Schrötter, Master of the Mint in Vienna, and known best through his discovery of amorphous phosphorus and his determination of the atomic weight of phosphorus; he died at the age of seventy-three years. A few days later Prof. Carius died at Marburg after a protracted illness. Although only forty-six years old, he leaves behind him the record of very numerous researches, of which those on the sulpho compounds, corresponding to glycerine and its derivatives, on the oxysulphides of phosphorus, on the action of hypochlorous acid on hydrocarbons, and on the analyses of organic chlorides, iodides, bromides, sulphides, and phosphides are best known.

THE *Times* of the 30th ult. contains a letter from its correspondent with the *Challenger*, dated "Zamboango, Jan. 31." The *Challenger* left Hong Kong on Jan. 6, and proceeded to the middle of the China Sea, where a series of temperature soundings was taken, the temperature at the bottom, 1,200 fathoms, being found to be 36° Fahr. This temperature is accounted for by Capt. Chimmo's statement, that the China Sea is cut off by a barrier, which rises to a height of between 800 and 900 fathoms below the surface of the water, from communication with the Antarctic Ocean. Passing along the west coast of Luzon, the *Challenger* entered a little enclosed sea extending from the north point of the island of Tablas to the strait between the north-east angle of Panay and the south-west point of Masbate. Here another series of interesting temperature soundings was taken, the temperature at bottom, 700 fathoms, being 51·7°. The temperatures generally in this Panay Sea were to a certain extent intermediate between those in the China Sea on the one side and the Zebu Sea on the other, leaving it uncertain whether the cleft in the barrier to the depth of 150 fathoms is between Tablas and Panay or between Romplon and Sabuyan. After visiting Zebu, near which some fine specimens of the beautiful sponge the "Venus' Flower-basket" (*Euplectella*) were trawled, the ship made for the small island of Comiguin, between Mindanao and Bohol, to inspect the active volcano therein. This volcano "was born on May 1, 1871," and now forms an irregular cone of 1,950 feet in height. From Comiguin the *Challenger* proceeded along the west coast of Mindanao to Zamboango, where a party of sportsmen were sent to camp out in the forest within riding distance of the ship. On leaving Zamboango, a run of about 2,000 miles was to be made nearly parallel with the equator, and only a few degrees to the north of Greenwich Island. Thence the expedition was to make one of the most important sections, through the Caroline and Ladrone Islands to Japan, where it was expected to arrive about the second week of April.

THE enterprise of the Scottish Meteorological Society we have had frequent occasion to refer to, and the practical as well as scientific value of the work it undertakes does it the greatest credit, especially when its narrow means is taken into consideration. One of its latest publications is a diagram by Mr. G. Thomson, Fishery Officer, Lybster, Caithness, showing for the months of July, August, and September, 1874, the catch and quality of the herrings, and the varying positions of the herring-ground in the district of Lybster, as also the meteorology of the district. The diagram, which has been revised by the secretary, Mr. Buchan, is ingeniously constructed and quite intelligible. There are two series of conjoined curves and tables, the first showing all details belonging to the meteorology of each day, and the second showing the catch and quality of fish. Underneath are a sketch of the coast and indications of the different fishing grounds occupied. The diagram, we believe, is intended for distribution among the various district fishery officers in Scotland, with the view of inducing some of them to prepare similar diagrams for 1875 for their own districts. With these, and the observations from twenty sea-thermometers which were presented by the Marquis of Tweeddale, as also of the weather during the coming season, results may be hoped for that will throw some light on the important question of the varying localisation of the fishings.

THE Committee of the forthcoming Geographical Congress at Paris have finished the distribution of the space allotted to the various countries in the *Pavillon de Flore* for exhibition; the geographical order has been adopted in locating the several nations. Russia, being the most northern, has been placed first; but magnificent rooms have been allotted to British exhibitors on the ground-floor. Everything has been done to ensure a splendid display of English science and industry, and great things are expected from the nation which, without any boasting, may be said to have done as much as many others put together to open the world to civilisation. The presidents of the English Committee are the Earl of Derby, Sir H. Rawlinson, and Sir Bartle Frere. Great interest is felt by the Society and the Committee in the Polar Expedition, and models of the two ships, of sledges, boats, &c., would be most particularly popular and very thankfully received.

THE Council of the Senate of Cambridge University upon the Grace which proposed to constitute a Syndicate for the purpose of considering what representations should be made to the Government as to the pecuniary and other relations subsisting between the University and the Colleges, are of opinion that it should be withdrawn; they think, however, that it is advisable to obtain the general opinion of the University on the following points:—1. What additional teachers or appliances for teaching are required in the different departments of University study. 2. How these teachers and appliances may be best supplied, whether by the individual Colleges or by the University, or partly by the one and partly by the other. 3. Whether by any improved organisation the systems of professorial and collegiate teaching may be made more efficient and be brought into closer relations with each other. 4. How the teaching in the University may be organised so as to give the greatest encouragement to the advancement of the several branches of learning. They therefore recommend that a Syndicate be appointed to consider these subjects. The Vice-Chancellor invites discussion of this report on Saturday next, at 2 P.M., in the Arts School.

A SYNDICATE has been appointed to consider what steps (if any) should be taken for establishing a Professorship of Mechanism and Engineering in the University of Cambridge.

The late Prof. Willis, by his will, offered to Cambridge University, for 1,200*l.*, the collections of models, instruments, and tools used by him as Jacksonian Professor. A Syndicate has been appointed to consider the expediency of purchasing the whole or part of the collections.

FOR some time past negotiations have been in progress between Prof. Charles F. Hartt, of Cornell University, and the Government of Brazil, in regard to a complete geological survey of that empire. It is now stated that the preliminaries have been completed, and that Prof. Hartt has been appointed director of the survey. His preparations for this work are ample, as he has made no less than four successive visits to Brazil with reference to the study of its general geology and ethnology. His salary is said to have been fixed at $10,000 a year. It is also announced that Prof. Caldwell, another member of the faculty of Cornell University, has been appointed to take charge of the agricultural branch of the survey.

IN reference to a note in *Dingler's Polytech. Journal*, mentioned in NATURE, vol. xi. p. 456, there is a second paper in

the valuable serial (2nd January part) on the part played by carbonic oxide gas in smoking. This treatise is by Dr. Vohl, and refutes Dr. Krause's opinion. He says: "It is evident from Dr. Krause's account that he is unaware of the experiments made by Dr. H. Eulenberg and myself as far back as 1871, which proved the presence of carbonic oxide in tobacco smoke. I cannot, however, agree with the idea that the physiological effects of smoking are to be in part or wholly attributed to this gas, as it varies greatly in the quantity in which it is present in smoke. This quantity is never considerable, and the effects in question must rather be ascribed to the volatile organic bases, which form while tobacco is burning. Dr. Krause owns himself that his analytical results are not exact, on account of the method he used in obtaining them; these results cannot therefore give any idea as to the quantity of carbonic oxide generally present in tobacco smoke, as neither the temperature nor the barometrical pressure was noted, nor was any account taken of oxygen and marsh gas."

THE Government has taken up the question of the protection of seals in the Greenland seal fishery; and a Bill has been introduced into Parliament by the Board of Trade, authorising the issue of an Order in Council prohibiting the capture or destruction of any kind of seal between such dates as may be specified in such Order, in any part of the area included between the parallels of 67° and 75° N., and the meridians of 5° E. and 17° W. Such Order is to be made whenever it shall appear that the other States whose subjects and vessels are engaged in the seal fishery shall make similar regulations. The great destruction of seals which has taken place of late years has seriously interfered with the success of the important industry. This year many of the vessels have returned "clean."

M. WALLON, the French Minister for Public Instruction, has visited the Lille Academy and Colleges, and was received with a great display of enthusiasm. He is said to contemplate many improvements in educational establishments in large provincial cities; these are to be tried first in the city where he was born, and which he represents in the National Assembly.

THE Council of the lately-established United Services College, Westward Ho, have resolved to introduce Natural Science into the regular school-work; in fact, to place it on an equal footing with Languages and Mathematics as a means of mental training. They have appointed as master Mr. Herbert Green, F.C.S., M.A., of Queen's College, Oxford, who has had some years' experience at Victoria College, Jersey. A laboratory will be at once fitted up under his supervision, and class-rooms will be added as required.

WITH regard to the statement quoted from Dr. Cleland's book on Animal Physiology (NATURE, vol. xi. p. 504), "that the presence of chlorophyll is as necessary for the production of organic matter in organisms as the presence of protoplasm is necessary for growth," a correspondent points out that fungi seem to be an exception to the rule. He has never seen it stated that Torula, for instance, contains chlorophyll, nor has he ever himself seen chlorophyll in Torula. It is generally agreed, he believes, that fungi do not contain chlorophyll or starch.

DR. JOHN CROUMBIE BROWN, F.L.S., author of a work on the Hydrology of South Africa, is preparing for the press a work which he intends to call "Reboisement en France." It will consist of records of the replanting of the Alps, the Cevennes, and the Pyrenees with trees, herbage, and bush, with a view to arresting and preventing the destructive consequences and effects of torrents, and will embody a *résumé* of Alexandre Surell's "Étude sur les Torrents des Hautes Alpes," with copious extracts.

THE Annual Meeting of the Royal Institution was held on Saturday last. Sixty-four new members were elected in 1874. The following gentlemen were unanimously elected as officers for the ensuing year:—President, the Duke of Northumberland, D.C.L.; Treasurer, George Busk, F.R.C.S., F.R.S.; Secretary, William Spottiswoode, M.A., LL.D., Treas. R.S. The Vice-presidents for the year are the Duke of Devonshire, K.G., Dr. Pole, F.R.S., and Dr. C. W. Siemens, F.R.S.

THE Iron and Steel Institute commenced its meetings yesterday; we hope to be able next week to give some account of the work done.

WE believe that Mr. Disraeli has promised to receive a deputation on the subject of the India Museum after the Whitsuntide holidays.

STEPS are being taken to obtain the assent of the Emperor to a proposal for holding an Imperial German Industrial Exhibition in Berlin in 1878.

MR. STANFORD is about to publish Part I. of "Vestiges of the Molten Globe," by Mr. W. L. Green, Minister of Foreign Affairs to the King of the Sandwich Islands. The work will be concluded in three parts, and will, we believe, contain some curious observations as to the formation of minerals, Mr. Green having had many opportunities of watching the process during his twenty-five years' residence beside the Hawaiian volcanoes.

MR. EDWARD B. AVELING, B.Sc. Lond., has been appointed Lecturer on Comparative Anatomy at the London Hospital Medical College.

MR. J. RAND CAPRON has reprinted from the April number of the *Philosophical Magazine* his paper "On the Comparison of some Tubes and other spectra with the Spectrum of the Aurora."

VINE culture in New South Wales is progressing very rapidly, the number of acres occupied for this purpose being 3,183 in 1873, against 2,568 acres in 1872, and the produce 575,985 gallons against 451,450 gallons. These figures relate only to the growth of grapes for wine-producing purposes, but a considerable area is devoted to the cultivation of the vine for other objects. In Western Australia also, where the soil and climate are eminently favourable to the growth of the grape, this pursuit is becoming more general.

MUCH information on the functions, the form, and the habits of the Octopus may be obtained from a small work by Mr. C. Mitchell, recently published by Messrs. Dean and Son. The structure and economy of the animal are, in it, explained in a particularly lucid and interesting manner, which will lead those who have the opportunity of seeing the Octopus in an aquarium for the first time, to form a far better idea of the somewhat shapeless mass presented to their view, than any amount of time spent in simply inspecting it at a distance. Some anatomical illustrations which are added will also be found very useful to any one who has the opportunity of obtaining specimens for dissection.

THE additions to the Zoological Society's Gardens during the past week include two Pig-tailed Monkeys (*Macacus nemestrinus*) from Java, presented by Mr. A. B. Gordon and Miss H. E. Humphreys; a Patagonian Conure (*Conurus patagonus*) from La Plata, presented by Mrs. Cabry; a Ground Hornbill (*Buceros abyssinicus*) from West Africa, a Concave-casqued Hornbill (*Buceros bicornis*) from India, received in exchange; a Hoffmann's Sloth (*Cholopus hoffmanni*) from Panama, purchased; two White-fronted Lemurs (*Lemur albifrons*), a Hairy Armadillo (*Dasypus villosus*), and four Upland Geese (*Chloëphaga magellanica*), born in the Gardens.

METEOROLOGY, ETC., IN MAURITIUS

THE following letter from Mr. C. Meldrum, dated "Observatory, Mauritius, April 2," to a friend in England, gives some interesting data tending to prove a connection between solar activity and the state of the weather. With his new instruments we may hope soon to have some most important results.

"Since December last the colony has been suffering from drought, and there is very little appearance of a favourable change. February has been the driest month since systematic observation commenced in 1852, and the rainfall for January and March has been far below average. If the present state of things continue long, the island will be hard up for water.

"Coincident with this drought there has been, as usual on such occasions, a great falling off in the number and violence of cyclones in the Indian Ocean. We copy here the log-books of all vessels arriving in port from India, Australia, the Cape, England, &c., so that no great storm can take place over the greater part of the ocean without our getting more or less information about it. Well, the hurricane season is nearly over, and we have heard of only two storms, one on the 24th of January away to the northward of us, and one on the 7th of March, away to the eastward of us, and neither of them seems to have been extensive or very violent, only two vessels having been involved in each. The season thus bears a remarkable contrast to the corresponding periods for 1871, '72, and '73, and furnishes another instance of the now oft-observed fact that when Mauritius suffers from drought the Indian Ocean is almost free from hurricanes. The neighbouring island of Réunion has fared as badly as Mauritius, and the log-books furnish evidence that the drought has prevailed over a wide area.

"The S.E. trade-wind has been blowing from S.E. to E. and E.N.E. almost without interruption during the last three months, and the barometer been unusually high and steady for the season, thus showing that from some cause or other the belt of calms and variables between the S.E. trade and the N.W. monsoon has not advanced so far to the south as it did in the years 1871–74.

"It is only now that I am enabled to keep a continuous record of the sun-spots, the photo-heliograph having been put up a fortnight ago, and being at work only for a week; but from observations made directly, as often as possible, it would appear that there has been a great falling off in the number and magnitude of the spots. If this is the case, then we have, as on many other occasions, a decrease of spots, a decrease of cyclones, and a decrease of rain all at or about the same time.

"Our latest telegraphic news, *viâ* India, states that severe cold prevailed throughout Europe. It would be very interesting to know the conditions of weather for the whole habitable globe during the last three months. Comparative meteorology—including the sun's—can alone throw light on the nature of the relations subsisting between weather changes and variations of solar activity.

"Although the sun-spots decreased considerably in January and February, yet one or two pretty large ones appeared towards the end of February, and on the 27th of that month, between 1 and 7 P.M. we had (for this latitude) a remarkable magnetic storm. I fancy next mail will bring us news of auroras and magnetic storms having been observed in different parts of the world at that time. We had no aurora here, but on the 25th, 26th, 27th, and 28th there appeared, shortly after sunset, long beams of light radiating from a point near the horizon at E. by N. (nearly opposite the sun). This of course is easily explained without an aurora or any fitful outburst on the sun, but I have noticed that these radiating beams, which are sometimes very gorgeous, and occasionally radiate from points near the poles, are much more frequent in some years than others—which may arise from different states of the vapour and clouds. Dr. Lyall, who took a series of observations in Madagascar about forty-five years ago, makes mention of them, and describes them under the name of Aurora.

"We have all the instruments at work now, except the thermograph, which has not arrived. I have been so much occupied with the putting up of the instruments and removing into the new Observatory, that I have had very little time for anything else. I wished to send to the Royal Society some papers, but I could not manage to get sufficient leisure to prepare them. In a short time we shall be in train, and I hope to resume the subject of periodicities, &c."

SCIENTIFIC SERIALS

THE current number of the *Quarterly Journal of Microscopical Science* commences with an account by Mr. Wm. Archer of a new freshwater sarcodic organism, named by the author *Chlamydomyxa labyrinthuloides*, which is illustrated by a superb folio-sized coloured plate, as well as an octavo one. The species is shown to be closely allied to *Labyrinthula* of Cienkowski. The matrix is enclosed in a multilaminate cellulose envelope, which at times appears to burst and give exit to protoplasmic contents, which emerge in an arborescent manner with hyaline prolongations, along which small fusiform protoplasmic masses travel.—Rev. M. J. Berkeley gives a short account of the Thread Blight of Tea, in which he describes the fungus producing it, although he is unable to name it because he has not had an opportunity of examining the fructification.—Mr. P. Kidd draws attention to the occurrence of spontaneous movement in the nucleoli of the epithelium of the frog's mouth.—This paper is followed by an excellent and illustrated account of the structure of the Pacinian corpuscles, considered with reference to the homologies of the several parts composing them, by Mr. Edward Schäfer, in which it is shown—assuming an ordinary nerve fibre to consist of the axis cylinder in the middle, surrounded by, first, the medullary sheath, or white substance; secondly, a delicate layer of protoplasm containing nuclei; thirdly, the primitive sheath (of Schwann); and lastly, the numerous laminæ of the neurilemma, which, however, encloses a layer of finely filamentous connective tissue—that the coats of the Pacinian are the layers of the neurilemma; that the sheath of Schwann surrounds the core, this latter being an expansion of the protoplasmic substance; that the medullary sheath, if not retained as such, disappears, and that the axis-cylinder becomes the central fibre.—Mr. A. W. Bennett gives an account of modern researches into the nature of yeast, specially noticing those of Reess and Cienkowski.—Prof. Lankester has a paper of special theoretical importance, on the Invaginate Planula, or Diplobastic Phase of *Paludina vivipara*; in which, after proposing the name "blastopore" for the orifice of invagination of those Planulæ which exhibit it, he proposes a a classification of Planulæ, which helps to simplify this intricate part of embryonic history. He divides Planulæ into two groups: *Delaminate* Planulæ, in which there is no invagination, but a splitting of the blastosphere to form the endo- and ecto-derm; and *Invaginate* Planulæ, which may be *embolic*, or have no food-yelk; or *epibolic*, possessing a "residual yelk." The Hydrozoa and Calcareous Sponges have delaminate planulæ; Amphioxus, Ascidians, many Mollusca, Sagitta, Echinodermata, and many Vermes have embolic invaginate planulæ; whilst in the third group are included many Mollusca, many Vertebrata, the Ctenophora, certain Vermes, and certain Arthropods.—Mr. H. C. Sorby describes the absorption spectrum of *Bonellia viridis*, and draws attention to a most striking point, namely, that there seems to be a constant ratio between the wave-lengths of the different bands in these spectra.—The number contains its usual excellent quarterly chronicle, notes, &c.

THE *Journal of the Chemical Society* (March 1875) contains the following papers, besides a large number of abstracts from other serials, already noticed in NATURE:—The formulæ of the alums, by S. Lupton. The author briefly states the formulæ given to the alums before they were finally designated as $A' B''' 2SO_4 . 12H_2O$ (where A stands for an alkali metal and B for a metal of the iron group). At present some chemists use this formula, while others double it into $A_2' B_2''' 4SO_4 . 24H_2O$. The cause of this variety of usage rests in the uncertainty attaching to the atomicity of alumium; this metal appears as a tetrad when combined with chlorine, bromine and iodine, but as a triad in its methyl and ethyl compounds. The author tried to obtain certain bodies similar to the alums in constitution, but differing in the number of molecules of water which they contain; the latter have often served to establish the formula of salts. Experiments were made with iron and ammonium alum, aluminium and potassium alum, and alumium and ammonium alum; these experiments are described, and the author arrives at the conclusion that the doubled formula as above is the correct one, as it seems that upon dehydration the residue $R_2' R_2^{iv} 4SO_4$ remains unaffected, and exists therefore in the ordinary alums in combination with 24 molecules of water.—On the colour of cupric chloride, by Walter Noel Hartley. This salt is almost invariably described as being of a green colour, but the author has found that the salt is only green as long as there is a trace of moisture about it; as soon as the salt is quite dry its crystals are

transparent, brilliant, and of a beautiful pale blue tint. A strong solution of the salt is deep green, a dilute solution blue. When the crystals are moist, they may be considered wetted with the dark green solution, and so their true colour is masked.—On the purification and boiling point of methyl-hexyl carbinol, by E. Neison.—This is followed by a note on the same subject from the pen of Prof. C. Schorlemmer. The two gentlemen agree pretty well with regard to the boiling point, which Mr. Neison finds to be at 181°–182° C., and Prof. Schorlemmer at 179°·5; the difference may probably rest upon the difference of thermometers.—The last paper is on the oxidation of the essential oils, by Chas. T. Kingzett.

Zeitschrift der Oesterreichischen Gesellschaft für Meteorologie, Feb. 1.—Dr. Julius Ucke, of Samara, contributes an abstract of his work, undertaken chiefly from a medical point of view, on the quantitative proportions of atmospheric oxygen in different climates, in relation to temperature, moisture, and density of air. The public have chosen certain localities as health-resorts long before science pointed them out as eligible, and although we cannot doubt that oxygen is a great healing power in these, the part it really plays remains to be determined by physiologists and pathologists. The present work merely opens the way to inquiry, and does not claim to go beyond the evidence of statistics. Samara is a health-resort remarkable for the rarity of diseases of respiration, but its climate is windy and not mild, and the changes of temperature are great, both daily and seasonal. The conditions of temperature, moisture, pressure, and wind, do not account for its healthiness. Two factors remain: oxygen and ozone. Oxygen only concerns us at present. In order to find the relative quantity of oxygen at any place, thermometric, barometric, and hygrometric data are indispensable. Thirteen European and three Indian towns and one American station were chosen. Data for Nice, Algiers, and Madeira were wanting. Bearing in mind the hygienic object of his task, Dr. Ucke takes as a measure of the quantities of oxygen the number of inspirations of a grown man in the course of a month of 30·42 days. In the absence of a normal standard, the mean of the results for the seventeen stations is used for comparison. He finds that in the whole year most oxygen is inspired at Samara, least at Seringapatam; that, taking all stations, the quantities are largest in winter, least in summer, except at Seringapatam, where spring gives the lowest figure. Also, that generally the quantities decrease from E. to W. These differences of course depend on the three factors, temperature, density, and moisture. The first two have by far the most considerable effect. The article is illustrated by various tables.

THE *American Journal of Science and Arts*, March.—The principal papers in this number are: On some phenomena of binocular vision, by Prof. J. Le Conte. The article has reference to the direction of the optic axes in sleep. Arguing from "double sight" in drowsiness, Prof. Le Conti concludes that the axes diverge.—The gigantic cephalopods of the North Atlantic, by A. E. Verrill. This is a continuation of a former article in which he records the dimensions of specimens captured within the last few years.—The trap rocks of the Connecticut Valley, by G. W. Hawes. This contains many analyses of dolerites and diabase.—On the comparison of certain theories of solar structure with observation, by Mr. S. P. Langley. (See following article.)—Notes on Costa Rica Geology, by W. M. Gabb. The area described—the district of Talamanca, consists of granite rocks on which rest beds of Miocene age, the granite being pushed up after the deposition of the Miocene.—Under the head of Scientific Intelligence is a description of a new order of Eocene Mammals, *Tillodontia*, by Prof. O. C. Marsh.—Report of progress of Geological Survey of Pennsylvania for 1874.—Notes on the transit of Venus.

Memorie della Societa degli Spettroscopisti Italiani, January 1875.—Mr. S. P. Langley, director of the Alleghany Observatory, contributes a paper on the comparison of certain theories of the structure of sun-spots with observation. He alludes to the so-called "crystalline" forms seen at times in the umbræ of spots, and to their lending confirmation to the views of those who regard the photosphere as a luminous covering of incandescent fluid, and the spots cooling matter in it. The author says that they are at first sight so confirmatory of this view that it was only after long study he had been led to think them assimilable to certain cloud forms in our atmosphere. A beautifully executed steel engraving accompanies the paper, showing the forms alluded to over the umbra of a spot; and they certainly put one in mind of certain forms of cirrus cloud. All the filaments of the penumbra are directed generally towards the centre of the spot; but while all are more or less curved, there is no common direction of curvature. Mr. Langley also remarks that the ends of the filaments are generally the brightest parts, and that it is difficult to resist the impression that they turn upwards at the extremities and appear as though lifting their points through some obscuring medium. One of the crystalline forms appears in great beauty on the spot. It is about 20″ long, and 10″ wide, and has the appearance of a plume or of finely carded wool: and the author asks if we are prepared to admit the existence of a body analogous to a crystal covering ten times the area of Europe. He also refers to sudden and abrupt changes in the direction of the filaments, apparently being due to the passage of one cloud stratum over another, and he remarks this disposition elsewhere in the spot giving a terraced appearance. He says: "It seems difficult to reconcile the bright, sharply-defined inner edge and the regular structure discerned in the umbra, with another view in which this umbra is a sort of stagnant pool formed by cold vapours or clouds which have settled there after depressing the general surface by their weight until the penumbral slope is determined;" and "The theory which regards cyclonic or vertical action as a prominent agent in determining the forms we have studied appears to be in closer accordance with observation than the former."—Father Secchi, in a note on the foregoing paper, remarks that at the edge of the sun, where the spot in question disappeared, there was seen an active prominence, and his further remarks are to be continued in the next number.—P. Tacchini contributes a paper on the condition of Italian and other observatories, giving the staff at each and their salaries. We extract the total payments to the staff and for instruments at the following Observatories:—

SOCIETIES AND ACADEMIES

LONDON

Royal Society, April 15.—"Researches upon the Specific Volumes of Liquids," by T. E. Thorpe. Communicated by Prof. Williamson, For. Sec. R.S.

I. *On the Atomic Value of Phosphorus.*

Hermann Kopp has shown that, as a rule, the specific volume of an element is invariable when in combination. Exceptions to the law occur, however, in the cases of oxygen and sulphur, each of which bodies has two specific volumes dependent upon the manner in which they are held in union. When contained "within the radicle," as in acetyl, C_2H_3O, oxygen has the value 12·2, but when existing "within the radicle," as in alcohol, it has the smaller value, 7·8. Sulphur, when "within the radicle," has the specific volume 28·6; when "without the radicle," it has the specific volume 22·6.

The cause of these variations may be thus stated in the language of modern theory:—When dyad sulphur and oxygen are united to an element by both their affinities, their specific volumes becomes respectively 28·6 and 12·2; when they are attached by only one combining unit, their specific volumes are 22·6 and 7·8.

Phosphorus is regarded by certain chemists as invariably a triad; others maintain that it is sometimes a triad, at other times a pentad. In the trichloride it is a triad, in the oxychloride and thiochloride it is a pentad. According to this view the two latter compounds possess the following constitution:—

```
     Cl             Cl
     |              |
  Cl—P=O         Cl—P=S
     |              |
     Cl             Cl
```

If, however, phosphorus is invariably trivalent, the oxychloride

and thiochloride must possess the following formulæ:—

$$\begin{array}{ccc} \begin{array}{l} Cl \\ | \\ P{-}O{-}Cl \\ | \\ Cl \end{array} & \qquad & \begin{array}{l} Cl \\ | \\ P{-}S{-}Cl \\ | \\ Cl \end{array} \end{array}$$

It is possible to decide between the two modes of representing the constitution of these compounds, if it be granted that the variation in the specific volume of oxygen and sulphur is due to the manner in which these elements are held in union. For if the phosphorus in the oxychloride and thiochloride be quinquivalent, the oxygen and sulphur must possess the greater of the two values, since both their combining units are united to the phosphorus; if, on the other hand, phosphorus be trivalent, the oxygen and sulphur must possess the smaller of the two values.

The author has determined the specific gravity, boiling-point, and rate of expansion of $P\,Cl_3$, $P\,O\,Cl_3$, and $P\,S\,Cl_3$, in order to ascertain the specific volume of the oxygen and snlphur in the two latter compounds, and consequently the chemical value of the phosphorus; and he finds that the specific volumes of the oxygen and sulphur are almost identical with the values given by Kopp for these elements when "without the radicle." It would therefore appear that the oxychloride and thiochloride must possess the constitution—

$$\begin{array}{ccc} \begin{array}{l} Cl \\ | \\ P{-}O{-}Cl \\ | \\ Cl \end{array} & \qquad & \begin{array}{l} Cl \\ | \\ P{-}S{-}Cl \\ | \\ Cl \end{array} \end{array}$$

and that the phosphorus in these bodies is to be regarded as a triad.

The author concludes by discussing Buff's hypothesis that the specific volume of an element varies with its chemical value; and he shows that in the case of phosphorus there are no reasons for the belief that this element has a variable specific volume.

Geological Society, April 14.—Mr. John Evans, V.P.R.S., president, in the chair.—Descriptions of new corals from the Carboniferous Limestone of Scotland, by Mr. James Thomson. In this paper the author described some forms of corals from the carboniferous limestone of Scotland, which he regards as new species, and as belonging to three new genera allied to *Clisiophyllum*. In the group which he names *Rhodophyllum* the calice is circular and shallow, the epitheca thin and smooth, the septa thin and numerous, and the columellar boss dome-shaped, slightly raised above the inner margin of the primary septa, and clasped by subconvolute ridges. The species referred to this genus are *Rhodophyllum Craigianum*, *R. Slimonianum*, *R. Phillipsianum*, *R. Argylianum*, *R. reticulatum*, and *R. ellipticum*. *Aspidiophyllum* has the calice generally circular, shallow; the septa forming thin laminæ for about half their length from within, when they become flexuous, and the columellar boss prominent and helmet-shaped. The species are named *A. Koninckianum*, *A. Huxleyanum*, *A. cruciforme*, *A. elegans*, *A. Hennedii*, *A. Danai*, *A. dendrophyllum*, *A. ellipticum*, *A. Pagei*, *A. scoticum*, and *A. laxum*. The third genus, *Kurnatiophyllum*, is most nearly allied to *Rhodophyllum*, but has the columellar space slightly raised above the inner margin of the primary septa, and crowned by bending or wavy lamellæ, some of which pass over the central space in sinuous folds. The species are described under the names of *R. concentricum*, *clavatum*, *Tyleranum*, *intermedium*, *ellipticum*, *Ramsayanum*, *Youngianum*, *Harknessianum*, *lamellifolium*, *bipartitum*, *octolamellosum*, *Haimianum*, *Edwardsianum*, and *Davidsonianum*. In a specimen of *Aspidiophyllum Huxleyanum* the author noticed in the open interseptal space a small tube, four lines long, around the inner margin of which there was a group of oval bodies, which, from their close proximity to the inner margin of the primary septa and their form, he is inclined to think may be ova.—On the probable existence of a considerable fault in the lias near Rugby, and of a new outlier of the oolite, by Mr. J. M. Wilson. The author called attention to what appeared to him to be a great fault in the Lower Lias at the village of Low Morton, near Rugby, where a sandpit is worked against the face of a steep hill to a depth of nearly fifty feet. The sand in the valley, as proved by wells and borings, is of great depth. Above the sand-pit is a clay-pit, and the author stated that the clay is bounded towards the sand by a highly inclined face of clay, against which the sand is thrown. This face of clay can be clearly traced for a distance of more than half a mile, running in a south-easterly and north-westerly direction. If continued to the south-east, it would pass close by Kilsby Tunnel, the difficulties met with in the construction of which may have been due in part to a continuation of the fault; whilst if continued to the north-west it would coincide generally with the valley of the Clifton Brook, the bed of which is also occupied by a great depth of sand. The line of fault thus passes between Rugby and Brownsover, and the author suggests that it is the cause of the presence on the summit of the Brownsover plateau of an extensive oolitic mass of Stonesfield-slate character. The line of fault continued further would connect with the Atherstone and Nuneaton fault, and agree with this in having its downthrow on the north-east side.—On a Labyrinthodont from the Coal-measures, by Mr. J. M. Wilson. The fossil referred to in this paper was from the Leinster Coal-measures, and was regarded as probably belonging to the genus *Keraterpeton* of Prof. Huxley, although the outer posterior angles of the skull do not appear to have been prolonged into cornua.—On *Cruziana semiplicata*, by Mr. J. L. Tupper; communicated by Mr. J. M. Wilson. In this paper the author gave a detailed description of a slab of unknown origin, but said to have been obtained from a workman at Bangor, containing several specimens of the fossil described by Salter under the name of *Cruziana semiplicata*. From his examination of the specimen the author seemed inclined to ascribe to *Cruziana* an animal origin, and to regard it rather as fossilised animal structure than as a cast of the track left by the feet of some animal passing over the surface of the sand.

Geologists' Association, April 2.—Mr. Wm. Carruthers, F.R.S., president, in the chair.—Remarks upon geological boundary lines, by Horace B. Woodward, F.G.S. The author believes a tendency exists to overlook the broad classification of lithological characters, and to adopt lines of a palæontological nature. The identity of organic remains is no absolute proof of contemporaneity. In identifying the age of a formation the test of superposition, as a rule, is decisive; and the main facts of palæontology must first be worked out from the stratigraphical succession of the rocks. Still the value of palæontology cannot be disputed, and if we cannot identify formations far separated as synchronous when the fossils are similar, we may parallel successive faunas. Our formations, when looked at in the large way, must be taken to represent deposits of essentially similar character, and characterised by a particular assemblage of fossils. The more we learn of the history of our own strata and those of foreign countries, the less evidence do we see of breaks in the conformity of succession.—Notes on the probable depth of the Gault sea; or, an endeavour to ascertain the relative depth of the sea during the Gault period, by comparing the representative fossil genera with recent forms, by F. G. H. Price, F.G.S. The author is disposed to consider that the depth of the sea in which the Lower Gault was deposited did not exceed 100 fathoms.

Meteorological Society, April 21.—Dr. R. J. Mann, president, in the chair.—Mr. Scott read a paper, "Notes on sea temperature observations on the coasts of the British Islands." He said that it mainly related to the connection between sea temperature and the take of fish on the coasts, and he noticed the investigations formerly carried on by the Dutch and that now in progress under the direction of the Scottish Meteorological Society. He read a letter from Mr. F. Buckland on the subject, which, however, proposed a scheme of action which would entail heavy expenditure, while at present there was no satisfactory record kept of the take of fish on any of our coasts except those of Scotland. Mr. Scott then said that he had had some observations of sea temperature taken at some stations in the West of England and on the coasts of the Irish Sea, and had received some observations from Mr. W. Dymond and from Mr. N. Whitley, and he submitted some monthly mean temperatures from a few stations. He also stated that both the Trinity House and the Commissioners of Irish Lights had kindly consented to have observations taken at certain lightships, and that instruments had been supplied for the purpose, and the inquiry was in progress. In conclusion, he mentioned the steps taken by the German Government to investigate the temperature, &c., of the sea on their Baltic and North Sea coasts, and expressed a hope that our Government would undertake a similar inquiry.—Mr. Pastorelli read a paper on the errors of low range thermometers. He pointed out some of the difficulties which instrument-makers have to encounter in graduating thermometers from $32^\circ{\cdot}0$ to $-37^\circ{\cdot}9$, the freezing point of mercury, as there is no intermediate fixed point. He believed that fairly accurate thermometers could only be obtained by calibration.—

Mons. Louis Redier exhibited his new barograph, which was explained to the meeting by Mr. Symons.—Mr. Scott also exhibited Prof. Wild's pressure anemometer.

Physical Society, April 24.—W. Spottiswoode, F.R.S., in the chair.—Mr. J. Barrett exhibited an "auxiliary air-pump;" it is a modification of Poggendorff's arrangement for obtaining a Torricellian vacuum, and is allied in principle to the exhauster used by Geissler in the preparation of vacuum tubes.—Mr. Barrett also showed a hammer break for the instantaneous rupture of the current in the primary wire of an induction coil. It is impossible to explain it clearly without a diagram, but an upright swing hammer is kept constantly vibrating by the alternate action of a spring and the magnetised core.—Dr. W. H. Stone read a paper "On some points connected with wind instruments." He stated that discrepancies might be noted in the behaviour of air issuing from the side orifices of wind instruments. These discrepancies deserve attention, and may be accounted for by the laws of efflux. He showed that the stream of air from the side hole of a clarionet was sufficient to extinguish a candle, though the musical vibration was obviously in the main tube. It is usual to tune such instruments by introducing a resinous cement into the holes so as to diminish their calibre, but after a certain point is reached the rounded surface thus obtained ceases to produce an effect. If a short pipe of the same diameter as the orifice be now inserted, auxiliary vibrations are set up, and a definite note may be produced.. Dr. Stone was led to inquire whether the theorem of D. Bernoulli, or the particular part of it named after Toricelli, could be brought to bear on the question. The *vena contracta*, which in fluids reduces the efflux to 0·62 of the calculated amount, is also to be noticed in gases, and the nature of the effluent column of air is affected by three conditions: 1. The thickness of the wall in which the orifice is made. 2. The shape of the nozzle. 3. Friction in a long pipe. Some mathematical details were then given respecting these conditions, and it was admitted that the vibration in a musical tube must also exercise sensible influence. There are two functions in a side orifice in an instrument; the first is to cut off a portion of the tube, and by this means to raise the pitch; the second establishes a point of non-resistance in the wall of the tube, and thus acts by influencing the longitudinal vibrations. In the organ peculiar qualities of tone are often obtained by these side holes, as in the "Viol di Gamba" and "keraulophon" stops. In flutes, oboes, clarionets, and other instruments, much of the tone comes from the bell, even when the side holes are open. In instruments in which the holes are long, as in the bassoon, the holes themselves became separate vibrating tubes. This was shown by introducing tubes of different and increasing lengths, into an orifice in the side of an organ reed pipe. The friction at last became so great, and the secondary wave so strong, that the organ-pipe returned to its original pitch. A reed was also applied to a cylindrical tube, and it was shown that a sharp-edged orifice opened at the middle point of the tube rendered it impossible to produce any note until a cylindrical nozzle was introduced, when the octave was sounded freely. The general results proved that lateral holes had a double function, the pitch of the notes emitted varying with their size, shape, and length, the actual severing of continuity in the principal tube being a comparatively minor point. Dr. Stone then inserted three tubes varying in length from two to six inches in a cylindrical tube like that of a clarionet, at right angles to its length, the longest being placed at the centre of the instrument, and the shortest at one-eighth from the mouthpiece. The same note was produced when each tube was used singly and when the three were employed, and Dr. Stone expressed a hope that a series of experiments would render it possible to develop curves in which the co-ordinates would be the lengths of the additional tubes and their position in the instrument. He also considered that a new instrument might be produced in which the side orifices acted purely as nodal points by the assistance of friction and the contracted vein.

Anthropological Institute, April 13.—Col. A. Lane Fox, president, in the chair.—A paper, largely illustrated by diagrams, was read by Prof. Rolleston, F.R.S., "On the people of the Long Barrow period." The author discussed at great length the following points:—1. The evidence existing for dividing the Long Barrow period into three epochs. In the earliest one the dead were interred unburnt in chambers, *i.e.* in graves walled with upright flags and communicating with the exterior by a passage or gallery, or at any rate constructed so as to admit of successive interments. In those chambers was found the greatest amount of manganous discoloration. In the second period the dead were still interred unburnt, but in cists, *i.e.* in closed stone receptacles not intended to be re-opened, and having no gallery leading to the exterior. The third epoch of the Long Barrow period was distinguished, to the great regret of the craniographer, by the practice of cremation, a practice which, like that of burial in cists, and with even more probability, might be supposed to link the Long and Broad Barrow periods together. 2. The evidence for accepting what might be called the Ossuary theory for explaining the appearances met with in the Long Barrows, rather than the theory of successive interments as put forward by Prof. Nilsson, or the theory of human sacrifices and anthropophagy as suggested by the late Dr. Thurnam. What inclined Prof. Rolleston to the Ossuary theory was the fact that just those bones are found in connection most frequently which would, by virtue of their ligamentous or muscular connections, longest resist the dislocating effects of removal from a provisional to a permanent burial-place. 3. The evidence as to the mode of life prevalent in the Long Barrow period which the cranial and other bones of the persons buried or burnt in them furnished. Mr. Bertram F. Hartshorne exhibited and described objects of Pre-Hellenic age from Troy.

Berlin

German Chemical Society, March 22.—F. Gäss and C. Hell have observed a condensation of amylic aldehyde through the agency of carbonate of potash resulting in the formation of a body $C_{10}H_{18}O_2$.—C. Hempel has found amongst the products of oxidation of terpin a new monobasic acid, $C_8H_{12}O_4$, homologous with terebinic acid.—E. Prehn found that hydrochloric acid transforms mesaconic into citraconic acid.—E. Büchner, in distilling paramonobromaniline, has observed its transformation into aniline, dibromaniline, and tribromaniline.—R. Fittig and R. Mayer, continuing their communications on isomerism in the aromatic series, insist upon the transformation of all three bromophenols into mixtures of resorcin and pyrocatechin, a fact singularly affecting theoretical conclusions hitherto drawn from single experiments.—A. Schrohe observed allylene-sulphuric acid to yield not only mesitylene, but also acetone, by the action of water.—W. Lossen sent a short note on the reduction of metallic oxides by hydroxylamine, which is thereby transformed into N and H_2O.—C. Gosslich asserts that he has discovered a fourth isomeric bromobenzene-sulphonic acid.—H. Limpricht recommended measures of precaution to be taken in the determination of the solubility of salts.—D. M'Creath described substituted guanidines obtained through the action of anhydrides on guanidines, viz., benzoyl-triphenyl-guanidine, diacetyl-triphenyl-guanidine, and dibenzoyl-diphenyl-guanidine.—T. Jannasch has been able to transform bromomesitylene, $C_6H_2Br(CH_3)_3$, into tetramethylbenzene, a liquid isomeric with durene.—C. Liebermann and H. Troschke have studied the action of ammonia on alizarine. The products are compounds in which OH is replaced by NH_2, and 2OH are replaced by NH.—C. Liebermann and F. Palm exhibited crystalline compounds of hydrocarbons with the chloride and with the amide of picric acid.

April 12.—O. Brenken has studied what was generally considered as the melting of terchloride of iodine, and has found it to consist of a dissociation into monochloride and free chlorine.—P. Melikoff determined that at 77° ICl_3 is completely decomposed into ICl and Cl_2.—A. Michaelis and J. Ananoff, in treating $PCl_2.C_6H_5$ with zinc ethyl, have obtained diethyl-phenyl-phosphine, a liquid base, distilling at 222°, taking up 2HCl and 2Cl. Oxide of silver, exchanging O against Cl_2, produces an oxide with the latter body. $PC_6H_5(C_2H_5)_3I$ is a well-crystallised compound. Similar bodies have been obtained by the action of zinc methyl on phosphenyl-chloride.—A. Michaelis, by treating $PCl_2C_6H_5$ with PH_2 and water or alcohol, obtained a yellow powder of the formula $C_6H_5 - P = P - OH$, diphosphobenzol corresponding to a diazobenzol.—E. Benzinger, heating phosphenylic acid, $C_6H_5 . PO(OH)_2$ with nitric acid in sealed tubes, has obtained a crystalline mononitrophosphenylic acid, which with tin and hydrochloric acid yields the corresponding amido-acid.—H. Lange, in passing toluene and PCl_3 through a red-hot tube, was unable to produce phosphobenzyl-chloride, but obtained stilbene only.—A. Michaelis, who has lately expressed the constitution of phosphorus acid thus: $HPO(OH)_2$, defends his view against a paper lately published by Zimmermann.—F. Kammerer has fixed the melting-point of perchloride of antimony as − 6° C.—H. Köhler and B. Aronheim have treated iodide of isopropyl and

chloride of benzyl with sodium, thus obtaining $(CH_3)_2CH.CH_2C_6H_5$, phenyl-isobutan.—H. Hübner proved that benzoic acid can liberate nitrobenzoic acid from nitrobenzoate of barium, although the latter is the stronger acid of the two. The experiment consisted in heating the solutions to 80°.—H. Hübner and C. Rudolf have obtained an ethenyl-phenylenediamine, $C_6H_4{\genfrac{}{}{0pt}{}{NH}{N}}\!\!>\!C.CH_3$, by treating orthonitroacetanilide with tin and glacial acetic acid.—O. Billeter has transformed sulphocyanate of phenyl into the sulphide by treating it with sodium-amalgam. Lead allyl sulphydrate and chloride of cyanogen have yielded allyl sulphocyanate to the same chemist; it is converted into the isomeric mustard-oil on distillation.—H. Limpricht communicated researches on derivatives of the three amidosulphobenzolic acids.—W. Weith, by heating chloride of ammonium with methylic alcohol to 280° for ten hours, has transformed it completely into trimethylamine and tetramethylammonium-chloride.

April 26.—Researches were read by A. Burghardt, on bibromobenzoic acid; by H. Glassner, on paraiodosulphotoluene, $C_6H_3.CH_3.I.SO_3H$; by T. Ebell, on nitrobenzonaphthylamide, $C_{10}H_6.NO_2.NH.CO.C_6H_5$, which was found to combine with iodide of amyl; by F. Meinecke, on derivatives of benzanilide; by E. A. Grete, on derivatives of metabromotoluene.—H. Hübner defended modern chemistry against attacks launched against it by Prof. Kolbe, and showed the insufficiency of the proofs hitherto furnished for the existence of four nitrobenzoic acids, four bihydrobenzene, and four bromobenzene-sulphonic acids. These doubtful cases of isomerism, which, if true, would be opposed to Kekulé's benzene theory, were also vigorously attacked by experiments published by A. Ladenburg, as well as by P. Griess and by E. Nölting. The constitution of benzene derivatives, viz., $C_6H_4Br.CH_3$ and $C_6H_3Br.NO_2.CH_3$, also formed the subject of a communication by E. Wroblewsky.—Mr. P. Siljeström defended his opinion on the density of gases under diminished pressure against that expressed by Mr. Mendelejeff.—A. Stutzer has tried the action of nitric acid on the fibre of grasses, and not finding benzene derivatives amongst the products, concludes that the fibre does not contain aromatic bodies preformed.—Dr. Ewald described an improved method for determining urea with hypobromite of sodium by ordinary volumetric analysis.—V. Mering reported on the action of digestion on sarcosine, arriving at the conclusion that urea and uric acid are *not* diminished in quantity in the urine of individuals fed with sarcosine. This is contrary to the observation published by Schultzen some years ago.—E. Fischer, in reducing a diazo-compound, $C_6H_5 - N = N - NO_3$, with bisulphite of sodium, and treating the resulting compound, $C_6H_5 - NH - NH.SO_3K$, with chloride of benzoyl, obtained the first of a new class of bodies:

$$C_6H_5 - NH - N(CO.C_6H_5)_2$$

that is, an ammonia, NH_3, in which one H is replaced by an amido-group, NH_2. He calls this class of bodies *hydrazines*; the body whose formula is given above is dibenzoylated phenylhydrazine. By the action of water and hydrochloric acid it yields benzoic acid and a base, phenyl-hydrazine, $C_6H_5 - NH - NH_2$, which forms well-defined crystalline salts with HCl, &c.

PARIS

Academy of Sciences, April 26.—M. M. Frémy in the chair.—The following papers were read:—On ascents to great heights, by M. Faye. M. Faye advocates strongly that the Academy should forbid any balloon ascent beyond 7,000 metres of elevation; he considers that any observations that might be made beyond that point will not be of any greater value than those up to that limit, and will certainly not outweigh the danger to life. He thinks that all aëronauts will respect the Academy's decision.—On the determination of ordinary alcohol when mixed with methylic alcohol, by M. Berthelot.—A note by M. A. Ledieu, on thermo-dynamical machines.—A note by M. Marès, on the results of the experiments made by the Commission investigating the diseases of vines in the Hérault.—A note by M. Dumas, on the use of alkaline sulphocarbonates against Phylloxera.—A note by M. F. de Lesseps, on the methods to be employed for the maintenance of ports.—A note by M. L. Saltel, on the geometrical principle of correspondence of M. Chasles.—On the curves of the order n with a multiple point of the order $n - 1$, by M. B. Niewenglowski.—On the development of the perturbating function according to the multiples of an elliptical integral, by M. H. Gylden.—On binauricular perceptions, by M. F. P. Le Roux.—On the determination of methylic alcohol in the presence of vinic alcohol, by MM. Alf. Riche and Ch. Bardy.—On the spiroscope, an apparatus for the study of auscultation, of the anatomy and physiology of the lungs, by M. Woillez.—A note by MM. G. Hayem and A. Nachet, on a new method of counting the blood-corpuscles.—On the wine-growing districts attacked by Phylloxera in 1874, by M. Duclaux.—M. Dumas then announced to the Academy the loss which science has sustained by the death of M. Anton. Schrötter, secretary to the Academy of Sciences at Vienna.—On the precipitation of silver by protoxide of uranium, by M. Isambert.—On the action of platinum and palladium upon the hydrocarbons of the benzenic series, by M. J. J. Coquillion.—A note by M. Peslin, on the law of diurnal and annual variations in the temperature of the soil.—On the theory of storms, by M. Cousté.—A note by M. U. Gayon in reply to M. Béchamp's paper on the spontaneous alterations in eggs.—On the helminthological fauna of the coasts of Brittany, by M. A. Villot.—On a new intermediary type of worms (*Polygordius?* Schneider), by M. Edm. Perrier.—On the ornamentation of striated wood-fibres and their relation to ordinary spotted fibres in the wood of certain species of Conifera, by M. G. de Saporta.—On the glacier deposits of the inferior valley of the Tech, by M. E. Trutat.—On the differences in the rising and setting of Mercury, Venus, Mars, Jupiter, and Saturn, as stated in the *Journal du Ciel* and in the *Annuaire du Bureau des Longitudes*, by M. J. Vinot.—On a method of re-establishing the concordance of the solar with the civil year, by M. Crampel.

BOOKS AND PAMPHLETS RECEIVED

BRITISH.—A Manual of Diet in Health and Disease: T. King Chambers, M.D., F.R.C.P., &c. (Smith and Elder).—The Journal of the Iron and Steel Institute, 1874 (E. and F. N. Spon).—Electricity; its Theory, Sources, and Applications: John T. Sprague (E. and F. N. Spon).—Researches in Chemical Optics: John H. Jellett, B.D. (Dublin University Press).—Journal of Proceedings of Winchester and Hampshire Scientific and Literary Society. Vol. i. Part iv. 1874 (Winchester, Warren and Son).—Meteorology of West Cornwall and Scilly, 1870 to 1874, and Observations on Sea Temperature, 1872 to 1874: W. P. Dymond, F.M.S. (Falmouth, Wm. Tregaskis).—An Address delivered by the President of the Meteorological Society at the Annual Meeting, January 20, 1875.—Journal of the Quekett Microscopical Club (R. Hardwicke).—Perthshire Society of Natural Science. Sixth Annual Report.—On Protoplasm: James Ross, M.D. (R. Hardwicke).—Commercial Handbook of Chemical Analysis, by A. THURSDAY, MAY 13, 1875

LORD HARTISMERE'S VIVISECTION BILL

THE Bill brought forward in the Upper House by Lord Hartismere for regulating the practice of Vivisection deserves special attention on account of its being the first important legislative attempt to restrict the prosecution of physiological research.

It enacts that it shall not be lawful for anyone to perform a vivisection except in a place which is registered in pursuance of the proposed Act, the registration being in such form and under the management of such persons as the Secretary of State shall appoint. The registration certificate is to be renewed once a year; it may be cancelled at any time on its being proved that any provision of the Act has been contravened, and the place registered may be visited at any time by any inspector of anatomy. Complete anæsthesia is compulsory, and curare is not to be deemed to be an anæsthetic. The Secretary of State may grant special licenses for the performance of vivisections in which anæsthetics are not employed; there shall be paid in respect of every such license a sum not exceeding ten pounds, and each license is to continue in force for six months.

In the framing of this Bill there is a serious misrepresentation of the true requirements of the case. The source of error lies in the fact that it is taken for granted that there is only a single class of physiological workers. Such, however, is not the case; there are two distinct classes, and although we agree with the tenor of the Bill as far as one class is concerned, we are certain that it would so severely affect the other that its results would be seriously detrimental to the prosecution of physiological research in this country.

Among ourselves there are several scientific men who devote part of their life to the study of the problems of the vital mechanism. Some do so from the inherent interest of the subject; others from a desire to obtain a further insight into pathology and disease generally. In the course of their investigations it is now and then absolutely essential for the completion of a line of argument, or for the acquisition of the knowledge of the collateral phenomena attending some previously recorded result, that an experiment or experiments should be performed on a living animal. Those whose mental development leads them to conduct investigations of this character are frequently peculiarly unwilling to do so in public institutions. It is their spare minutes, when they are entirely their own masters, that they employ in their favourite study. Are they to be compelled, against their natural dispositions, either to obtain an official license for the performance of these experiments on their own premises, or, as an alternative, conduct them in some previously specially licensed establishment which is under the control of others? The necessity for such a method of procedure would deter many an excellent worker from commencing investigations which he recognises to be so much impeded by *legal* restrictions. There might as well be a tax on astronomers directing their telescopes to any special planet or to the moon. The public may feel certain that students of the class to which we refer will never go beyond the limits of the innate laws of sympathy present in all civilised humanity. Such do the most valuable work in a scientific point of view; and any legislative measure which in any way affects them injuriously, either by rendering the whole research apparently too formidable at the outset, or by the introduction of unpleasant details during its prosecution, ought most strenuously to be resisted. The power of turning to a practical end the results of inductive reasoning is the basis of the British nature. Inductive research cannot be had for money; it is always a labour of love; it is not fair to put impediments in the way of it.

The class of physiologists to whom legislative restrictions with regard to vivisection do apply, is the teachers. There is no doubt that those who assert that the performance of vivisectional demonstration is unnecessary will have the sympathy of the majority. A fact may be learned from books or by practical demonstration. As far as natural science goes, the extra time which has to be expended in obtaining the results practically is generally quite made up for by the accessory details introduced, which are many of them omitted in written or verbal descriptions. Observation is a far more sound basis on which to start fresh work than the knowledge acquired from books alone. The student should therefore, where nothing counter indicates, have the opportunity of repeating, on his own account, the experiments he reads of. In the case of practical physiology, however, another consideration has to be introduced. Here the subjects of experiment are sentient beings, and the question comes to be whether the advantages of the practical verification of fully described phenomena which involve pain are counterbalanced by the injustice done in the production of the pain itself. We think not, and are therefore fully in favour of legislative restrictions on the powers of those who wish to employ living animals for the purpose of demonstration, even where anæsthetics are employed, because there is a tendency among those who are in the habit of repeating experiments to neglect those parts of them which are not absolutely necessary. But any measure which in any way impedes original work, as does the Bill before us, ought, in our opinion, to be strongly opposed.

GEIKIE'S "LIFE OF MURCHISON"*

II.

Life of Sir Roderick I. Murchison, Bart., F.R.S. etc. Based on his Journals and Letters. With Notices of his Scientific Contemporaries and a Sketch of the Rise and Growth of Palæozoic Geology in Britain. By Archibald Geikie, LL.D., F.R.S., Director of H.M. Geological Survey of Scotland, and Murchison Professor of Geology and Mineralogy in the University of Edinburgh. 2 vols. Illustrated with Portraits and Woodcuts. (London: John Murray, 1875.)

MR. MALLET, in a memoir published in the *Philosophical Transactions* (vol. 163, p. 147), which has attracted attention as much for the boldness of its tone as for anything else, has laid down the dictum that no sound progress can be made in geology unless the investigator be also mathematician, chemist, and physicist. Now, Murchison was none of these, yet he would be a

* Continued from p. 3.

bolder man than the writer of that memoir who should affirm that no sound progress was made in geology by him.

It is true enough, no doubt, as Prof. Geikie says, that "he was not gifted with the philosophic spirit which evolves broad laws and principles in science," and he therefore contributed nothing to this branch of geology. It is strange, in fact, that when he did express any opinion on debated theories—and he did so frequently with vehemence—he generally took that side which the advance of science has condemned as untenable; so that the only assistance he gave to theoretical geology was that of affording the holders of any new theory the notorious advantage of having some one to argue against. He made no speculations himself, but only discussed those of others. In fact, "he had the shrewdness to know wherein his strength lay. Hence he seldom ventured beyond the domain of fact, where his first successes were won, and in which throughout his long life he worked so hard and so well. In that domain he had few equals."

But for the observation of geological facts there is no necessity for a universal acquaintance with science, however great an advantage such an acquaintance may be; and this is proved by the successful labours of many a field geologist—by the example of Wm. Smith, so often called the Father of English Geology, who had no such advantages, and by Murchison himself, as these pages of Prof. Geikie abundantly show.

Yet there are qualities requisite for such work as Murchison's, which are rarely so abundantly possessed as by him; they are, a keen perception of the really essential features of a district, or, as Smith somewhat quaintly expressed it, "a fine eye for a country;" a power of correlating apparently dissimilar objects; and last, not least, an untiring industry and perseverance that persist in pursuing an intricate subject until it is fully mastered. These appear in all his work, and are well brought out in his "Life."

Although the name of Murchison is now indissolubly connected with Palæozoic rocks, he did not begin his geological work among them, but among those easier Secondary rocks in which the order and arrangement is so much clearer. His first work, in 1825, was a "Geological Sketch of the North-western extremity of Sussex and the adjoining parts of Hants and Surrey," which was certainly up to the average geology of the time, and gave promise of better things in the future. Indeed, when it was thus seen that he had the ability, and intended to be a worker in the science, he was elected to the secretaryship of the Geological and fellowship of the Royal Society, rather from the hope of what he would do than from what he had done—and fortunately the hope was not disappointed.

His next work was the determination of the age of the coal-beds of Brora on the east coast of Scotland, in connection with which he described those remarkable remains of Secondary rocks so marvellously preserved on both sides of Scotland, and which have lately been the subject of such admirable and beautiful memoirs by Judd and others.

The difficulties he found in understanding some of the rocks he saw on this tour induced him to seek the co-operation of Sedgwick, and thus commenced that long and happy association of two great men, which, though clouded for a time, cannot be said to have been entirely broken up. We may mention here that these volumes are enriched with portraits of some of the chief geologists that have been or are, and nothing more life-like, as far as we know the originals, could be desired.

Another of his early works, in conjunction with Sedgwick, was an account of the structure of the Eastern Alps, which raised much discussion among European geologists, who have not finally accepted the conclusions they contended for—as, for instance, as to the age of the remarkable Gosau beds which they considered to be Tertiary—though they are now generally regarded as Cretaceous.

During all this time he had, like most geologists, avoided as much as possible what he called the "interminable Grauwacké." In the summer of 1831, however, he started with his wife and "two grey nags" to make the first attempt at unravelling the complicated features of these slaty rocks. He determined to begin at the top and trace the succession downwards. In this way he made out satisfactorily that summer the limits and range of the Ludlow rocks. Subsequent summers were devoted to the same work, and arrangements of the Silurian rocks of increasing accuracy were from time to time presented to the Geological Society until his final conclusions made their appearance in the "Silurian System."

On the controversy concerning the nomenclature of the Palæozoic rocks, which led to the painful estrangement between Murchison and Sedgwick, Prof. Geikie throws every possible light, and renders the whole matter perfectly clear. We cannot but think, however, that Sedgwick had more cause for complaint than Prof. Geikie would seem to admit, for if Murchison had no intention to disparage Sedgwick's work, he really, to a great extent, ignored it in comparison with his own. The facts are these. Murchison, in working downwards, described as Lower Silurian the rocks which formed his Caradoc and Llandeilo series, but without defining any satisfactory base line. Sedgwick, in working upwards, described as lying above a series of, at that time, unfossiliferous slates, a set of rocks which he called the Bala group, or Upper Cambrian. Now, though both these geologists went in company over both districts, they failed to discover that these two series were the same—in fact, they pronounced them distinct. Hence, when it was discovered that the one series, the Upper Cambrian, rolled over an anticlinal into the other, the Lower Silurian, each geologist blamed the other for the error. But in the meantime it was ascertained that the fossils were identical, and hence, "zoologically speaking," two different names could not be employed. If, as Murchison supposed, there was a total absence of organic remains beneath these disputed rocks, much might be said in favour of associating them in name with the fossiliferous Silurian rather than with the azoic Cambrian. Yet the manner in which this was done by Murchison, so fully explained by his biographer, leaves little surprise at Sedgwick's indignation, but only that he should have been so long in discovering the drift of what was being done. For in 1842 Murchison writes him a letter, begging the whole question by calling them Lower Silurian, as if there could be no possible idea of calling

them Cambrian, and bidding Sedgwick, if he would retain the latter name, to find some fossiliferous beds *below*. This is followed by the complete dropping out of the name in his "Russia;" and when in after years a series of Lower Fossiliferous beds *were* found, Murchison still sought to include them under the title of Silurian. It is astonishing that Sedgwick should for so long have failed to perceive the drift of these changes—and when he did at length arouse himself he found half his Cambrian system gone, and not unnaturally felt that his friend had "stolen a march on him." Such appears from the data afforded by this work to be the true account of this controversy. In late years, however, chiefly owing to the labours of Mr. Hicks, much new light has been thrown on the succession of faunas in these earliest rocks, and it has been shown that by no means the greatest break in life occurs at the base of the Llandeilo rocks as described by Murchison; and it is therefore probable that the true limits of the two systems will have yet to be re-adjusted under the light of the new facts.

The "Silurian System" is a masterpiece of industry, perseverance, and comprehensiveness, and will be a classical work so long as Geology is a science; it is undoubtedly Murchison's *magnum opus*, and it led directly to those other researches by which he has also contributed so much to our knowledge. Thus it was, on being told that plants had been found in Silurian rocks in Devonshire, that he persuaded Sedgwick to accompany him there, when they found that the so-called Silurians were really of Carboniferous age—but on what did they rest? on a series of rocks with a peculiar assemblage of fossils, which gave them great difficulty at first, but which at last they recognised as a new system, the Devonian, with which they boldly classed the Old Red Sandstone, though no community of fossils had yet been proved. This last step, however, was fully justified, by Murchison's finding in Russia the fishes of the one associated with the shells of the other, and thus the Devonian system was settled on a firm basis.

The received classification, however, of the Devonian rocks was called in question by Prof. Jukes shortly before his lamented death; he assigned the greater part of them to the Lower Carboniferous system, and Prof. Geikie considers it to remain now an open question. He says: "They who have given most attention to this part of geology will probably most readily admit that, whether in the way of contest or not, the question must be reopened; that the accepted classification is far from being satisfactory, and that Jukes did a great service by boldly attacking it, and bringing to bear upon it all his long experience in the south of Ireland, which gave him an advantage possessed at the time by hardly anyone else." Whatever controversy, however, there may be on the classification of particular rocks, there can be no doubt that there is a distinct epoch of life between the Carboniferous and Silurian, and this Murchison and Sedgwick together first defined and established.

It was for the study of the Silurian system, too, that Murchison was led into Russia, and here it was that he found that large development of rocks containing a special fauna overlying the Carboniferous, to which he gave the name of Permian, and which formed the subject of several subsequent researches.

We are greatly indebted to Murchison for the introduction of good names into Geology. It was he who first proposed the use of geographical terms, so happily illustrated in "Silurian," which introduce no theory and no incongruity, such as is involved in calling rocks "transition rocks," or speaking of the Old Red Sandstone as represented by a clay. This method of nomenclature has been widely adopted and is now almost universal, and it has the further advantage of carrying with it information as to the locality where the series is typically developed.

The minor works of Murchison, in the shape of papers and addresses during the time that these "systems" were being worked out, were numerous, and, with the exception of his "Geology of Cheltenham," almost entirely confined to those Palæozoic rocks that had now become so familiar to him. But he brought forward now, not only his own researches, but those of more humble workers also, always giving them due credit. Amongst the most remarkable of these were the discovery of the curious crustaceans of a new type, now known as Eurypteridæ, in the Upper Silurian rocks of Lesmahagow, by Dr. Slimon. Another was the discovery of fossils in the ancient crystalline rocks of the Highlands, by Mr. Peach, which led ultimately to the last of the valuable series of labours that Murchison performed. In the same category as the above must be placed the publication of "Siluria," in which he embodied from time to time, not only his own original researches and additions to them, but the works of all who had laboured in that field, by which the work became at the same time less his own, and more comprehensive than the "Silurian System."

Finally, in the chapter entitled "The Foundatio Stones of Britain," Prof. Geikie gives an account Murchison's last geological work, that of making out the structure of the extreme north-west of Scotland, and discovering there the oldest rocks in Britain. Here, in 1858, he discovered three series of rocks, each overlying the one below unconformably, and it was in the upper of these three that Mr. Peach had found Lower Silurian fossils. If, then, the second be the Cambrian, the lowest must be a series still older. To this he gave the name of Fundamental Gneiss, but afterwards classed it with the Laurentian system of Sir E. Logan, which had been hitherto unrecognised in Britain. This work, however, valuable as it is, is of a different kind to that which made Murchison what he was—a master-builder in Geology.

His chief work consisted in uniting vast masses of rocks stretching over miles of country, variously characterised lithologically, and containing numerous different suites of fossils, into large comprehensive groups; in grasping the features by which many minor periods are united into single systems; in laying down the broad outlines in which the complete geological picture is to be traced. This is the work wanted at the birth of a science; it requires a peculiar power of mind, possessed in large degree by Murchison, who thus deservedly takes rank among the founders of Geology.

We leave Prof. Geikie's work with regret. Like him in writing it, we live again in reading it, with this hero of science; and no one can rise from its perusal without a deeper interest in the progress of knowledge, and especially of geology. A man of great power, thoroughly

devoted to the advancement of science, and pursuing it with energy and discretion, is an example of which we cannot have too many; and the history of Murchison shows how much valuable material may yet be lying dormant in some who have as yet shown no devotion to anything but pleasure and sport.

MARSDEN'S NUMISMATA ORIENTALIA

Marsden's Numismata Orientalia. A New Edition. Part I. "Ancient Indian Weights." By Edward Thomas, F.R.S. (London: Trubner and Co., 1874.)

THIS is the first part of a new edition of "Marsden's Numismata Orientalia," on an enlarged scale, and is the reproduction of an essay published some years ago. As it treats of the earliest information that has come down to us of the system of monetary weights in use amongst ancient Eastern nations, it is considered as an appropriate introduction to subsequent numbers, upon the coins of various Eastern countries, to be contributed by other authors.

Mr. Thomas's essay is a work of considerable interest, not only as regards the information contained in it relating to ancient Indian weights and coins, but also for its philological and ethnological information. The earliest and most important authority cited is from the Sanscrit text of the original code of Hindu law by Manu, the exact date of which is undetermined. Although portions of it are assigned by some authorities between the twelfth and thirteenth centuries B.C., yet the body of the compilation is more generally referred to a period about 400 B.C.

The Indian weights mentioned in the Code of Manu were those of Central India, south of the Himalayas, and comprised between the rivers Indus and Ganges. They were in use after the occupation of this country by the Aryans, whose invasion from the northwest is referred to a period as early as 1600 B.C. Mr. Thomas, however, claims a still earlier origin for this system of ancient Indian weights, and that they were already in use before the Vedic Aryans entered India. The old system appears to have been based on the weight of native seeds. The principal unit was the *Rati*, the seed of the wild liquorice plant. A second unit or standard of weight is stated to have been the *Másha*, a small wild bean, which is also mentioned in the Code of Manu as a food grain. The following tables of monetary weight are taken from the ancient record, and include the smaller seed-grain weights, which, in the original Sanscrit text, are made to originate and lead up to the larger weights in metal, together with the smaller sub-divisions of the seed-grain unit. Their equivalent weight in Troy grains is given by Mr. Thomas as computed from the mean of experimental weighings of the several seeds, and as confirmed from the ascertained weights of less ancient Indian coins.

TABLE I.—*Minor sub-divisions of the Unit, the* Rati.

			Troy grain.
Rati (seed of wild liquorice)			= 1·75
Yava (barley corn husked)		= 1/3 Rati	= 0·5833
Gaura-sarshapa (white mustard seed)	= 1/6 Java	= 1/18 Rati	= 0·0972
Raja-sarshapa (black mustard seed)	= 1/3 Gaura	= 1/54 Rati	= 0·0324
Likhya (small poppy seed)	= 1/3 Raja	= 1/162 Rati	= 0·0108
Trasarenu (mote of sunbeam)	= 1/8 Likhya	= 1/1296 Rati	= 0·00135

TABLE II.—*Multiples of the Unit, the* Rati.

			Troy grain.
Silver.			
Rati			= 1·75
Mashaka (small wild bean)		= 2 Rati	= 3·5
Dharana Purana	= 16 Mashaka	= 32 Rati	= 56·0
Salamana	= 10 Dharana	= 320 Rati	= 560·0
Gold.			
Masha		= 5 Rati	= 8·75
Suvarna	= 16 Masha	= 80 Rati	= 140·0
Pala, or Nishka	= 4 Suvarna	= 320 Rati	= 560·0
Dharana	= 10 Pala	= 3200 Rati	= 5600·0
Copper.			
Karshapara		= 80 Rati	= 140·0

The fanciful introduction of the "very small mote which may be discerned in a sunbeam passing through a lattice" throws doubt on the practical use of this table; but there appears abundant evidence of the continued use of seed-grain weights in India from a very early period.

The earliest record of Indian measures of capacity, which are only incidentally mentioned in Manu, are quoted from a Sanscrit work for which very high antiquity is claimed. It gives the measures of *ghi*, or clarified butter, in equivalent weights of the *masha* and other multiples of the *rati*.

As to Indian measures of length, though permanently based upon natural units, as the digit, span, and cubit, yet the same seed principle is applied in Manu to the small sub-divisions of the digit. Thus, taking the cubit as the unit, the sub-divisions are stated to have been as follows:—

Hosta (cubit).	
Vitasti (span)	= 1/2 Hosta
Angula (digit)	= 1/12 Vitasti
Yava (very small barley corn)	= 1/8 Angula
Yuka	= 1/8 Yava
Liksha (poppy seed)	= 1/8 Yuka
Balagra (hair's point)	= 1/8 Liksha
Renu	= 1/8 Balagra
Transvarenu (mote of sunbeam)	= 1/8 Renu

The *Hosta*, or cubit, was thus equal to twenty-four digits, or six palms. Mr. Thomas does not assign any particular length to the cubit of *Manu*, but inferentially defines its length from the determined length of the Sikendari *gaz*, or yard, at the end of the fifteenth century, which is rather more than thirty imperial inches. This *gaz* is stated to have been equal to 41·5 digits, and the digit is computed as being equal to 0·72976 inches. This would make the ancient Indian cubit equal to above 17·5 inches.

Mr. Thomas considers that the system of Indian weights here described was indigenous, and he differs from Don V. Queipo, who traces the derivation of the Indian system of weights to primary Egyptian sources. He prefers the "wise reserve of Boeckh," who expresses himself in the following terms:—

"In cases where the weights of measures of different nations are found to be in a precise and definite ratio one to the other—either exactly equal, or exact multiples and parts of each other—we may fairly presume, either that the one has borrowed from each other, or that each has borrowed from some common source. When the ratio is inaccurate or simply approximative, it is to be treated as accidental and undesigned."

The more recent discovery, since the publication of Don V. Queipo's work, of the unit of ancient Egyptian weight, the *Kat* = 140 grains, equivalent in weight to the Indian copper unit, the *Karshapara*, to the gold *Suvarna*, and to one-fourth of the silver *Suvarna*, tends to confirm Don V. Queipo's hypothesis of the identity of the practical units of Egyptian and Indian weights. The Indian

cubit of 17·5 inches, divided into twenty-four digits, is also almost identical with the ancient Egyptian natural cubit of six palms and twenty-four digits. But it appears to be now impossible to determine whether these Indian units were derived from the Egyptian, or both from an earlier common source; although we may fairly assume that this natural cubit was of the same length as that used by Noah before the Deluge. Mr. Thomas's hypothesis of the lesser Indian unit of weight and of length, and of the scale of multiples and parts, is, however, probably correct, as being derived from natural and local sources.

OUR BOOK SHELF

Arboretum et Fleuriste de la Ville de Paris. Description culture et usage des Arbres, Arbrisseaux et des Plantes herbacées et frutescentes de plein air, et de serres, employées dans l'ornementation des Parcs et Jardins. Par A. Alphand. Folio, pp. 110. (Rothschild, Paris.)

ORNAMENTAL gardening, among other things that added to the attractions of the city of pleasure, was greatly fostered during the latter part of the reign of Napoleon III., and does not appear likely to languish under the Republic. The magnificent publication, "Les Promenades de Paris," by the author of the book now before us, is a costly work, known to comparatively few people in this country. We presume that the present volume is regarded as an appendix or supplement to the work named, otherwise we cannot account for the publication of what is little more than a catalogue of names in so unwieldy a form.

An enumeration of the plants grown for the embellishment of the parks and gardens of Paris, in a handy octavo form, would be welcome to almost every lover of horticulture; but the object of the compiler of the "Arboretum et Fleuriste" was doubtless such as we have indicated. It is printed on one side of the paper only, and the matter arranged in columns, giving the names, native countries, soil, use, height, form of leaves, colour of flowers, &c., of the various plants. As a horticultural catalogue the work is fairly well executed, but, like most gardening books, it contains errors that have been copied from book to book, though they were cleared up long ago. In the first part of the work the author has indulged in an attempt to introduce a reform in botanical nomenclature; why it was not carried through we are not told, probably for the reason that, however desirable reformation may be, this one would scarcely receive any support from botanists. It consists in giving all substantive specific names an adjectival form, and, a less justifiable act, of changing the terminations of good Latin names. Thus, for example, *Pinus Coulterii*, *Hartwegii*, and *Fenzlii*, become *P. Coulterea*, *Hartwegea*, &c. Objections might be urged against this course; but why should we change *Benthamiana* and kindred names into *Benthamea?* And *Pinus inopsea* for *P. inops* is quite inadmissible.

The information under the several headings is usually not inaccurate, but somewhat loose. Thus, under the genus *Magnolia*, Pennsylvania is given as the native country of *M. acuminata*, Carolina of *auriculata*, Virginia of *glauca*, and so on; whereas these trees have a much wider range of distribution. Again, under *Cratægus coccinea*, we are told that the specific name indicates scarlet flowers; but the flowers are white, and the fruit scarlet. But as it is not a botanical work, it is scarcely fair to criticise it by a botanical standard, though it is scarcely excusable to give North Africa as the native country of *Calla Æthiopica*, New Zealand of *Caladium esculentum*, &c. *Libocedrus decurrens* is referred to *Thuja gigantea*, and the true *T. gigantea* to *T. Menziesii*; but the synonymy of these plants has long been cleared up even in gardening books.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Prof. Willis's Mechanical Models

THERE is a slight error in your account of the disposition of Prof. Willis with regard to his mechanical models in your last impression (p. 14).

Prof. Willis did not put any price upon his models; but by his will, dated May 11, 1872, directed that his "mechanical models" should be "offered to the University of Cambridge at a price to be fixed by the valuation of some competent appraiser to be nominated and chosen" by his executors.

In consequence, we have caused the models to be so valued, and fixed upon the sum named (1,200*l.*) after due consideration of the means of the University and the requirements of the estate.

A Syndicate was appointed on April 29 to consider whether the whole or a part of the collection shall be purchased. In the event of the University declining to purchase, the portion rejected will be offered for sale by public auction or private contract.

Ants and Bees

IN NATURE, vol. xi. p. 306, Mr. Alfred George Renshaw refers to and criticises a paper on "Ants and Bees," lately read by Sir John Lubbock, and assumes, or seems to assume—and the language quoted justifies such assumption—that Sir John advanced the idea that bees have no means of communicating knowledge to each other.

It seems strange to me, who have been all my life familiarly acquainted with the working of bees, that anyone should doubt their power of communicating knowledge. The very idea there advanced, that "if the bees had the means of communicating knowledge, those bees would have told the others in the hive where they could obtain a good store of honey with a very little trouble, and would have brought a lot back with them," I have seen proved and illustrated hundreds of times.

Bee-hunters understand this faculty in the bee perfectly well, and turn it to a good account. Going to a field or wood at a distance from tame bees, with their box of honey, they gather up from the flowers and imprison one or more bees, and after they have become sufficiently gorged, let them out to return to their home with their easily-gotten load. Waiting patiently a longer or shorter time, according to the distance of the bee-tree, the hunter scarcely ever fails to see the bee or bees return, accompanied with other bees, which are in like manner imprisoned, till they in their turn are filled, when one or more are let out at places distant from each other, and the direction in each case in which the bee flies noted, and thus, by a kind of triangulation, the position of the bee-tree proximately ascertained.

Those who have stored honey in their houses understand very well how important it is to prevent a single bee from discovering its location. Such discovery is sure to be followed by a general onslaught from the hive unless all means of access is prevented. It is possible that our American are more intelligent than European bees, but hardly probable; and I certainly shall not ask an Englishman to admit it. Those in America who are in the habit of playing first, second, and third fiddle to Instinct will probably attribute this seeming intelligence to that principle.

It seems to me, and I think it may be so concluded on scientific principle, that there is no difference, except in degree, between the intelligence, or whatever it may be called, of man and of lower animal life. If the honey-bee, the ballooning spider, the agricultural ant, or the dog, is governed wholly by instinct, then it seems reasonable to infer that man is also governed by instinct. If all the actions of lower animal life are automatic, on what principle shall we say that man's are not automatic? If man builds his house, and, intending to furnish it and lay in a stock of provisions, ascertains from his neighbour where he can get the most at the cheapest rate, does he act on any principle different from the bees, who build their house and jointly or separately ascertain where the best stock of honey can be obtained?

In regard to selfishness, I think the bee has the advantage of

man. In my own garden, where I have had standing always from ten to fifty swarms, and over which I thought I was watching with almost a fatherly affection, I have learned how utterly selfish I was in looking forward to autumn, when, by the destruction of the industrious and unselfish bees, I could lay in for my own consumption what they had so laboriously gathered in the summer to sustain each other through the winter. I learned, from their unselfishness, to divide with them, always leaving enough to sustain the colony till the spring should again bring the flowers.

I think, too, that both Sir John Lubbock and your correspondent are mistaken as to the object of beating pans, sounding horns, and making other hideous noises in hiving bees. The object is not, as Sir John intimates, originally to drive away evil spirits, or to assert ownership, as indicated by Mr. Renshaw. It is simply, as everyone knows who ever thumped on a pan, sounded a horn, or yelled through a speaking trumpet on such an occasion, to drown the voice of the queen or guides who are to conduct the swarm to the new home which members of the community who had been sent out, as the Israelites sent forward Joshua and others, had found for them.

Mr. Renshaw's law is probably good, but does not apply in the case trying. JOSIAH EMERY

City of Williamsport, Pa., U.S.

Flowering of the Hazel

IT was with great interest that I read the communication from F. D. Wetterhan, in NATURE, vol. xi. p. 507. But I cannot help expressing quite a different opinion as to the bearing of the interesting fact that proterandrous and proterogynous individuals are to be found in the same locality. From the structure of the flowers and from insects never visiting the stigmas, I am convinced that the hazel is a strictly anemophilous plant; that the red colour of its stigmas is solely an effect of chemical processes connected with the development of the female flowers to maturity, just in the same manner as in the female flowers of the larch-tree and some other Coniferæ; and that likewise the coexistence of proterandrous and proterogynous individuals in the hazel relates solely to the influence of the wind, and not at all to the agency of insects.

Whilst in Primula, Pulmonaria, and many other entomophilous plants, so admirably treated of by Charles Darwin, two kinds of individuals, viz., long-styled and short-styled ones, have originated from the positions of the anthers and the stigmas diverging in different individuals in opposite directions—among the anemophilous plants in *Juglans regia* * and *Corylus avellana*, among the entomophilous ones in *Syringa vulgaris* † and *Veronica spicata*,‡ two kinds of individuals, namely, proterandrous and proterogynous ones, have originated from the periods of development of the anthers and stigmas diverging in different individuals in opposite directions. The effect in the two contrivances has been the same, cross-fertilisation not only between different flowers, but also between different branches, having become indispensable.

In dimorphous species, this cross-fertilisation, as is known, is effected by the visiting insects touching with the same part of their body the anthers of the long-styled and the stigmas of the short-styled form; and with some other part of their body the anthers of the short-styled and the stigmas of the long-styled form. This kind of intercrossing can apparently never be effected by the wind; whence long-styled and short-styled (dimorphous) species are never to be found among anemophilous plants. But in these the coexistence of proterandrous and proterogynous individuals produces the same effect, the pollen-grains of the proterandrous individuals, of course, being transported by the wind only to the stigmas of the proterogynous ones, and *vice versâ*.

Lippstadt, May 1 HERMANN MÜLLER

Variable (?) Star in Sextans

THE following may be of interest to the readers of your Astronomical Column :—

About 2¼° *north* of, and a little *preceding* λ Hydræ (4 mag.), is a star marked 5th mag. in Harding's large *Atlas Novus Cælestis* (1822). This is now invisible to the naked eye, and of about mag. 7. It is 19662 in Lalande's Catalogue, in which it is rated at 4½ mag. It seems difficult to understand how excellent observers like Harding and Lalande could have made a mistake of 2 magnitudes in the estimation of a star's brightness, particularly as it is closely preceded by a 7½ mag. star (Lalande, 19646). So that probably this star has faded since 1822. Its position for the beginning of the present year is in R.A. 9h. 57m. 30·46s., and N.P.D. 98° 58′ 0″·42.

Equilibrium in Gases

MR. NICHOLS, in NATURE, vol. xi. p. 486, advances the opinion that in a vertical column of gas at rest the temperature does not tend, as generally believed, to become equal throughout, but that such a column is in a state of thermal equilibrium when the temperature diminishes at the rate of 1° centigrade for every 233 feet of ascent (or 1° Fahr. for every 129 feet). This is a question of thermo-dynamics, and I am not mathematician enough to offer any opinion on it from the theoretical point of view, but it seems inconsistent with well-known meteorological facts. Were it true, there would be, as Mr. Nichols points out, a constantly renewed tendency for the lower strata to flow upwards in consequence of their higher temperature and consequent relative expansion. Such a tendency is no doubt very common, but Mr. Nichols's theory would require it to be universal, and it does not appear to exist in the absence of direct solar heating. Cumulus cloud is an infallible proof of the presence of ascending columns of air, and according to the report of the Austrian Polar Expedition in NATURE, vol. xi. p. 415, cumulus is never seen in the Arctic winter; and I have somewhere read the same respecting the Siberian winter. The true cause of the accumulation of heat in the lower atmospheric strata, to which upward currents and the formation of cumulus is due, is, I have no doubt, that usually assigned—namely, that the atmosphere is more pervious to the heat of the sun than to heat radiated back from the earth; so that, as I think Tyndall expresses it, the sun's heat is caught as in a trap. JOSEPH JOHN MURPHY

Old Forge, Dunmurry, Co. Antrim, April 30

Curious Phenomenon of Light

ROWING on Loch Lomond recently, above Luss, there were seen to the north-west, at an apparent distance of about 100 yards, two bright lines of prismatic light, 60° apart and on the level of the water. Their length seemed to equal the breadth of a rainbow. Their violet ends were towards each other, and were joined by a line of dull white light, to the middle of which the sun and the spectator were at right angles. Standing in the boat, the colour and brilliancy were lost, and only a diffuse white light was visible. The time was 10 A.M. The sun was hot, the sky cloudless, the air hazy and still, and the loch a mirror. This apparition fled before our approach for some minutes, till dispelled by a slight breeze, which rippled the water.

Luss WM. M'LAURIN

Destruction of Flowers by Birds

I ENCLOSE some flowers of the common blackthorn, that I suppose to have been snipped off by birds. The bushes were growing in the outskirts of a wood, in a very sequestered situation (near Dunstable). The upper branches appeared to have chiefly suffered. The grass below was quite conspicuously starred with the fallen blossoms. I can hardly think that human intervention had anything to do with it. R. A. PRYOR

Hatfield, May 5

[In the accompanying specimens the limb of the calyx (carrying the stamens and petals) had been neatly cut away from the tube.]

OUR ASTRONOMICAL COLUMN

ORBITS OF BINARY STARS.—Dr. Doberck, of Colonel Cooper's Observatory, Markree, Co. Sligo, has published the results of a new investigation of the elements of the revolving double star σ Coronæ Borealis, in which measures to the end of 1872 are included. The period of revolution is increased to 843 years, which is longer than any yet assigned to this star. Dr. Doberck's comparison of his orbit with the measures of the late Rev. W. R. Dawes affords another proof of the remarkable excellence of that astronomer's observations, particularly in the last

fifteen years of the period over which they extend, when he had the command of comparatively large telescopes; and a similar remark applies to the measures of Baron Dembowski, who during upwards of twenty years has produced work of the greatest value in this department of astronomy. Dr. Doberck also gives us a provisional orbit for τ Ophiuchi, which Sir William Herschel in 1783 considered the closest of all his double stars; and after appearing single to Struve with the Dorpat refractor in 1825, was oblong in 1827, and is now an easy object. The period assigned is 185 years, with a peri-astron passage, 1820·63; the semi-axis, 1″·11.

THE STAR LALANDE 19662 (SEXTANS).—Mr. J. E. Gore, of Umballa, Punjab, in a letter printed in another column, directs attention to the probable variability of this star. It was observed by Lalande, 1798, April 10, "Histoire Céleste," p. 330, where its magnitude is entered 4½, as in the reduced catalogue published by the British Association (which, by the way, as well as the other two catalogues prepared at the instance of that body, is unfortunately becoming scarce). It appears in Heis's Atlas as a 6·7; but after searching through the modern catalogues where it was likely to be included, we have only discovered a single meridian observation by Lamont in his Zone 314, on 1845, April 5, when it is called 7·8. It does not occur in Argelander's "Uranometria," nor was it observed by D'Agelet, Bessel, or Santini.—Another of Lalande's stars, No. 23726 in Corvus, is in all probability variable. He estimated it 7½, 1795, May 10, and Bessel in May 1824 called it 8; Heis, however, saw it as a *fifth* magnitude. What is the actual degree of brightness? The star's position for the commencement of the present year is in R.A. 12h. 37m. 2s., and N.P.D. 103° 10′·3.

THE STAR 61 GEMINORUM.—The Rev. T. W. Webb has remarked the probable variability of a small companion of this star, distant about 1′, and not far from the circle of declination to the south (estimated angles from 160° to 190°), and appears inclined to identify it with Smyth's companion of the 9th magnitude, for which he gave, 1835·85, position 110°·0, distance 60″. Smyth's estimates of magnitude down to 9 may be generally relied upon, though for smaller stars he is often wide of the mark, according to our present standard. It is very possible that he may have caught one of the minor planets close to 61 Geminorum; his angle, though it has only his lowest weight, differs considerably from recent estimations for the faint star. Our principal object in referring to the Rev. T. W. Webb's remarks is, however, to suggest that 61 Geminorum may be itself variable; D'Agelet considered it 6 in October 1784. Piazzi observed it ten times on the meridian, and estimated it 7·8; it is 7 in Lalande, 6·7 in Taylor's volume for 1834–35, 6 in the "Uranometria" and Heis's Catalogue, 6·5 in "Durchmusterung," and 6·3 in the Radcliffe Observations, 1870. The deep yellow colour noticed by Smyth, and now stated to have disappeared, may perhaps be considered by some readers as an indication in the same direction.

COMETARY ASTRONOMY.—The *Astron. Nach.*, No. 2,034, contains a fine series of observations of the faint comet discovered by Coggia, 1874, August 19, taken at the newly-erected observatory of Col. Tomline, Orwell Park, Ipswich: it extends to the middle of November, and will no doubt be of material service in the final determination of the orbit. (The position of the Orwell Park Observatory is in long. 4m. 55·8s. E., and lat. 52° 0′ 33″). Vienna observations of the same comet appear in No. 2,035 of the above-named periodical, but extend only to October 19: they are accompanied by positions of Winnecke's Comet (1874, April 11) to June 17, and of the comet detected by Borrelly (July 25) to October 19.—In No. 2,036, Dr. Sandberg has given elements of the elliptic comet of Tempel, 1873, II., which will be preferable to any hitherto published. It will be remembered that this comet, near the preceding aphelion passage, experienced very heavy perturbations from the action of Jupiter, having approached that planet in January 1870 within 0·35 of the earth's mean distance from the sun. In the instantaneous ellipse at perihelion, 1867, May 23, the period of revolution was 2,080 days: at the last passage by the same point of the orbit, the perturbations had increased the period to 2,179 days. Other elements for 1873 are: semi-axis major, 3·2889; semi-axis minor, 2·9169; perihelion distance, 1·7695; the period in years is 5·965, so that we may expect to see the comet in the spring of 1879 under similarly favourable conditions for observation to those of 1867 and 1873.—In No. 2,037 we have definitive orbits (parabolic) for Comet 1870, IV., which was observed for only seven days, and of Comet 1871, II., both by Herr Schulhof, of the Observatory at Vienna. As the manner in which the elements are expressed may not be readily understood by the uninitiated in such calculations, we transcribe the orbits in the form that has so far been adopted in our catalogues. The perihelion passage is expressed in Greenwich time, and the longitudes are from mean equinox at commencement of the year.

*LECTURES AT THE ZOOLOGICAL GARDENS**

III.

May 6.—Mr. Garrod on the Deer Tribe.

THE Deer may be defined as those Ruminant Artiodactylate animals in which deciduous horns are developed, and the young are spotted. Some, namely the Musk Deer (*Moschus*) and the Water Deer (*Hydropotes*), never have antlers; in both these the young, however, are spotted, as they are not in any of the hollow-horned Ruminants.

The degree of development of the antlers is closely related to the size of the species. In the small Pudu Deer and the Muntjacs they are simple or but slightly branched; whilst their branching is very considerable in the large Reindeer and Wapiti. The typical antler seems to consist of a main stem or beam, with a small basal, anteriorly directed tyne, the brow antler. The apex of the beam bifurcates, one branch being directed forwards, and a little external to the brow antler; the other starts from the inner side of the posterior surface. In one well-marked group, the *Elaphine*, the anterior of these upper branches is inconsiderable and does not branch, the posterior enlarging and branching in most—becoming palmated in the Fallow Deer. The larger species of this elaphine section, including the Wapiti, Maral and Red Deer, possess a second brow antler; whereas in the smaller species this is not found (*e.g.* the Fallow, Formosan, Mantchurian, and Japanese Deer). In the Mesopotamian Deer, recently discovered by Sir Victor Brooke, which is intimately related to the Fallow, the palmation is found in the basal portion of the antler, including the brow antler, together with extra small tubercles very frequently found in that region.

In the group of Deer called *Rusine* the bifurcation is more equal, and when there is a further branching, the anterior as well as the posterior branch participates in the division. The brow antler is simple. This type of antler is found in its most uncomplicated condition in the Sambur of India, and the closely allied species *Rusa equinus*, *swinhoii*, &c. of the Malay region and

* Continued from p. 9.

Formosa, as well as in the smaller Axis, Prince Alfred's and Hog Deer. In the Siamese Deer, named by Mr. Blyth after Mr. Schomburgh, the brow antler is long, whilst each of the two branches of the short beam again divides in a very regular manner, the ultimate tynes being of nearly equal length. In Duvaucel's Deer, from India, the beam is longer than in the last-named species, and the branching is very similar, except that the posterior bifurcation is less developed than the anterior. This reduction is carried to an extreme in Eld's Deer, from Eastern India, where the anterior division of the antler is very large and curved forward, whilst the posterior is represented by a minute tyne. The gradation between these three forms was demonstrated by Mr. Blyth. In the Reindeer the general conformation of the beam very closely resembles that of Eld's Deer, but with this rusine peculiarity, the strangely palmated brow antler is double, as only elsewhere occurs in the elaphine type. In the American Roes a similar conformation obtains, the brow antler being small in the Virginian Deer and almost absent in the Mule Deer, which latter species in the branching of the beam very closely agrees with both Duvaucel's and Schomburgh's Deer.

The South American Guazupucu (*Blastocerus paludosus*), which differs considerably from the Mazame, a species generally supposed to belong to the same genus, has the anterior bifurcated tyne. This may be the modified brow antler, as may be the similar branch in the Chinese Elaphure discovered by the Père A. David, both these species having a simple, or comparatively simple, posterior beam, and no gland on the outer side of the metatarsus.

The interpretation of the affinities of the Roebuck by means of its horns is not easy. In that species there are three small tynes, the anterior being situated higher up than is usually the case with brow antlers, and the two posterior much like those of the Hog Deer. In the last-named species, however, the brow antler is not low, and it is not difficult to imagine it being carried a little further up. On this assumption the Roebuck is the only European representative of the rusine type.

The simple nature of the antlers in the Brockets of South America and the peculiar Muntjacs of the Indian region, in which the horns are attached on the top of elongated pedestals, makes it impossible to decide, from them alone, the forms to which they are nearest allied.

As far as the hornless Musk and Water Deer are concerned, Sir V. Brooke has shown in how many points they differ from one another; whilst Prof. Flower, at a recent meeting of the Society, has demonstrated to a certainty that the former of them is not at all related to the Chevrotains, which they so closely resemble in size and general contour, and with which they have generally been associated.

The horns of the Elk do not agree with any of the above-described forms. The fan-shaped palmation into which they spread is based on a radiating framework, and no specialised brow antler is to be seen.

With reference to the geographical distribution of the Deer, none are to be found in the Australian or Ethiopian region, the Barbary Deer being the only member of the group found in Africa at all, and that north of the Sahara. The Elk is found both in North America and Northern Europe, as is the Reindeer. The larger Elaphines are represented in North America by the Wapiti, and by several closely-allied species distributed throughout the Palæarctic region as defined by Mr. Sclater to include Europe, North-west Africa, and Asia with the exception of India and the Chinese Empire. The smaller Elaphines abound in Japan, China, and Formosa. The true Rusas are most numerous in India and the Indo-Malay Archipelago, the most recently discovered species, named by Mr. Sclater *Rusa alfredi*, having been obtained by the Duke of Edinburgh from the Philippines, whilst *R. Swinhoii* is from Formosa.

Mr. Swinhoe's new Water Deer abounds at and near Shanghai, whilst the equally peculiar Elaphure probably has its home in South-west Mantchuria, though it exists in large numbers in a semi-domesticated state in the Imperial Park at Pekin, together with commoner species. The Musk Deer comes from India and the country north of it, and the Muntjacs are found in India and China, as well as the intermediate regions. The Cervidæ are also represented in North America by the Virginian, Mexican, and Mule Deer; the Guazus, Guemuls, and Brockets replacing them in the southern continent.

(*To be continued.*)

THE IRON AND STEEL INSTITUTE

THIS Association may now be fairly considered as having become an established institution in the country, and is to be congratulated on the success it has achieved in its attempt to introduce something like scientific method into the important industries with which it is connected. It is undoubtedly doing excellent work, and if it adheres steadily to its purpose, and goes on as it has begun, it will help greatly in enabling our iron and steel manufactures to keep pace with the rapid progress which is being made on the Continent and in America.

As we have already intimated, the Institute held its annual general meeting in London on Wednesday, Thursday, and Friday, the 5th, 6th, and 7th inst. The Report which was read was very encouraging; the number of members is now 832, and the financial statement is highly satisfactory.

The Bessemer Medal for 1875 has been awarded to Dr. Siemens, F.R.S., in recognition of the valuable services he has rendered to the iron and steel trades by his important inventions and investigations. Besides a number of foreign gentlemen, Dr. Percy, of the School of Mines, was elected an honorary member. The next provincial meeting is to be held in Manchester early in September.

Mr. Lowthian Bell, after a short address, resigned the chair, to which Mr. William Menelaus was elected. The address of Mr. Menelaus was mainly concerned with recent improvements in the manufacture of steel. Mr. Menelaus has evidently correct notions as to the method by which the industries with which he is connected are to be made the most of. "As an iron maker," he said, "my mission has been to bring into profitable use the valuable inventions of Bessemer, Siemens, and others, and to apply the scientific research of men like Mr. Bell to the improvement of old and new processes."

On the evening of Wednesday Mr. Warrington W. Smyth delivered a valuable lecture on "The Ores of Iron considered in their Geological Relations." Mr. Smyth directed attention to the oxides as met with by themselves, or combined with water or carbonic acid, and which formed the great bulk of the material employed in iron making. First in order of the ores thus limited was magnetite. This mineral, with 72·41 per cent. when pure, was the fine rich ore which had been worked with great success for centuries in several of the Scandinavian mines. In Italy fine examples of magnetite were also found, as well as in several widely-separated places in North America. Magnetite only occurred in a few localities in Great Britain, amongst which the vicinity of Penryn, in Cornwall, and Hey Tor, near Bovey, in Devon, were mentioned. The next species noticed by the lecturer was hæmatite. This ore, so little recognised thirty years ago, was now too well known to require to be enlarged on. He next described the curious ores named bauxite and wöchenite, in which alumina takes the place of the sesquioxide of iron, turgite, göthide, limonite, chalybite, the last-named often mixed with other ores on

a large scale. The most important deposit of this last-named ore was contained in the range of veins occupying a length of some thirty miles in Somerset and North Devon, from the Raleigh's Cross westward to near Ilfracombe. Proceeding next to show the relationship between the oxides, the lecturer exhibited a specimen of ore having the appearance of chalybite or spathic ore, being covered with the large rhombohedral crystals characteristic of that species, but which the presence of the brown streak and of water and the percentage of iron proved to have been turned into brown ore. A fragment from the lodes of the Deerpark in Exmoor, next shown, had also lost its carbonic acid, had acquired oxygen and water, and actually become a different substance. It had been argued that the change commenced with the formation of the more hydrated species, and passed through successive stages to those with the least amount of water; but on that point evidence was as yet defective. The brown ores were undoubtedly (for the process might be watched in the workings) formed by another series of changes from pyrites through the sulphate of iron. The crystals of brown ore, in the form of pyrites, were among the best known pseudomorphs, and there were localities which invited the inference that this action had taken place on an important scale. Mr. Smyth, in concluding, said he would not, in the present brief sketch, venture upon the vexed question of the original deposition of the great northern masses of hæmatite, although strong arguments for their having been chalybite might be adduced from the occurrence of limestone fossils turned into red ore. He brought under notice another change of condition among the oxides of iron. It was a significant fact that magnetite was characteristic of the older formations—of those bodies of rock which had during the longest period of time been exposed to the influences which bring about metamorphosis and change of substance. In the Perran lode small portions of magnetite had been formed among the brown ores near the surface. In some of the Cornish copper lodes specimens of magnetic ore had occurred which looked very much as if they had been carbonates, and amongst the beautiful red ores of Siegen small grains of magnetite appeared to testify to a partial change, while there appeared to be sufficient grounds for believing that, in many cases at least, this last change in the degree of oxidation might be produced by the ordinary action of natural causes.

One of the most interesting papers from a scientific standpoint was that read on Thursday by Sir J. G. N. Alleyne, Bart., "On the estimation of small quantities of Phosphorus in Iron and Steel by Spectrum Analysis." This paper forcibly shows the valuable practical results which may follow from lines of pure scientific research. We shall return to this paper in a future number.

Mr. Lowthian Bell then read a long account of his visit to mines and ironworks in the United States. He began by saying that in the year 1871, one half of the iron produced in England was exported to foreign countries, and one-fourth of this half was despatched to the United States, in all about 750,000 tons. In the year 1874, however, the States only took 130,000 tons, and it was stated that during the three years the producing power of that country had risen from two-and-a-half millions to four millions of tons. Mr. Bell entered into considerable details on the subject of methods of transport in the United States. The railway system has grown into dimensions far exceeding those in England, the land of its birth. At the end of 1873 the United States had 70,651 miles of road, against only 16,082 miles in England. He calculates that 46,000 acres of timber fall annually to provide fuel for the charcoal furnaces. Less than 200 acres of a four-feet seam of coal, in the county of Durham, would produce the same weight of coke as is obtained from 46,000 acres of American forest. Coal is more abundant in the United States than in any other part of the world, and all kinds are found. In some places natural gas is used for puddling, re-heating, &c. Of pit-coal itself there are 192,000 square miles, as compared with 8,000 square miles in the United Kingdom; and Mr. Bell thinks it may be doubted where there is any similar area in the world in which a larger proportion of the surface is occupied by coal-bearing strata. From the position which the beds of anthracite coal occupy, it would appear as if, after their original formation, an enormous amount of lateral compression had been experienced by the districts in which they lie. This force has raised the strata into a succession of waves, as it were, the slopes of which vary from an angle of 20 to 45 degrees, and occasionally descending to a depth of 200 to 250 fathoms or more. In some cases this compressive power has been so great as to have forced one ridge back over its neighbour, to such an extent as to convert what is the floor of the seam in one place into the roof at another, and, from a similar cause, the quantity of coal which has accumulated at the anticlinal axes of some of these coal undulations is so great as to afford a face of forty to sixty feet, or even more, in thickness. In some cases denudation has carried off not only the sandstones and shales, but a portion of the coal itself; the bared edge of the seam is found immediately under the alluvial matter of the surface. He stated that there is a vast extent of carboniferous or mountain limestone in America, frequently very near the pig-iron works. Near Baltimore the shells of oysters, which are found in great abundance at Chesapeake Bay, are used. They contain 95 per cent. of carbonate of lime, and are a very inexpensive substitute for lime itself. The United States contains abundant quantities of iron ore of all kinds except the spathose ore, which is very scarce even in Europe. The ironstone of the liassic and oolitic seams, which furnish about one-third of the pig-iron made in the United Kingdom, seems to be entirely wanting in the States. Mr. Bell described the magnetic iron ore of Lake Champlain, its peculiarities, mode of deposition, &c., its abundance, and its freedom from deleterious ingredients; he remarked that the contents of the mines are chiefly obtained by open quarry work. The ore yields something like 67 per cent. in the Iron Mountain deposit. Mr. Bell, in treating of the blast-furnaces, referred first to the establishments which have been founded for promoting scientific training and education, and he spoke very highly of the earnestness and devotion which characterises those engaged in the mining and metallurgical industries of the States.

At Friday's meeting Mr. Bell read a paper on "The Sum of Heat utilised in smelting Cleveland Ironstone."

Other papers read on Friday were: "A brief account of an Underground Fire in the Wynnstay Colliery, Ruabon, and the measures adopted to extinguish it and to re-enter the workings," by Mr. G. Thomson. The fire became so unmanageable as to necessitate the sealing up of the shafts, after which explosions of gas took place, and the shafts were resealed, and so remained for a period in all of nearly five months. Preparations were then made for re-entering the mines, and this was successfully accomplished, and, after subsequent difficulties of a varied character had been overcome, the colliery resumed operations after a cessation of about seven months, and were now in full work again. The means used to effect the object, and a detailed explanation of all the operations, together with statistics of the temperature, the pressure, and the composition of the gases in the different shafts from time to time, were given in the paper.

On "The Manufacture of Bessemer Steel in Belgium," by M. Julien Deby, C.E., Brussels, and on "The Howard Boiler," by Mr. David Joy, of Barrow-in-Furness.

Altogether the meeting has been a satisfactory one.

*THE PROGRESS OF THE TELEGRAPH**

V.

We now continue our description of Wheatstone's electrical "Jacquard."

The rapid sequence of currents passed into the line-wire by the "Transmitter" are automatically recorded at the distant station by means of an apparatus called the "Receiver," or printer, which marks upon a continuous paper ribbon, as it passes through the instrument, the "dot" and "dash" code of the Morse alphabet, corresponding to the holes in the perforated Jacquard ribbon, as rapidly as the sequence of currents can be passed into the line. Two forms of this receiving instrument may be noticed: one shown in Fig. 22, in which the "dot" and "dash" code is represented by dots upon the paper ribbon upon either side of a central line, the lower line of dots being read as "dashes" and the upper line as "dots." The paper ribbon, mechanically advanced forward through the machine in a continuous manner, is passed under a shallow dish containing ink or other marking fluid. Two fine small holes are made through the bottom of this reservoir, in a position to correspond with the dots to be printed upon the ribbon as it passes underneath the reservoir. By reason of capillary attraction, the ink is prevented from passing through these apertures. Two electro-magnets, one on either side of the ink-reservoir, actuate two needles, which are adjusted so as to be depressed by the action of the current, and, dipping into the reservoir, pass into the holes, and carry a small dot

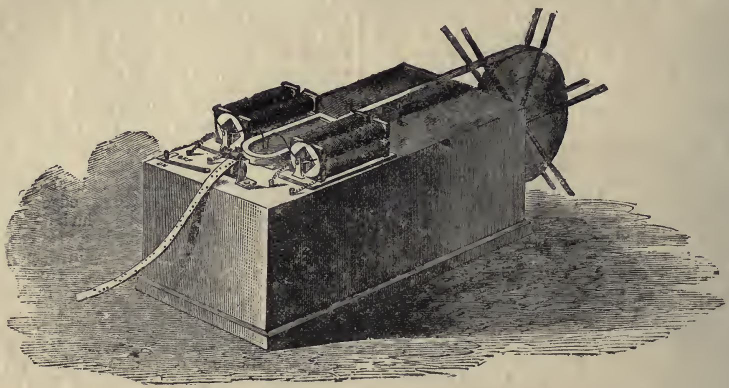

FIG. 22.—Wheatstone's "dot" automatic "Printer."

of ink through on to the paper ribbon; thus the mark is printed as a "dot" or "dash," according as the respective needle is depressed without any friction or mechanical resistance beyond that of the needle dipping into the ink held in the capillary tubes. The electro-magnet coils are so arranged that only the respective needles are acted upon by the currents as they flow from the positive or negative poles of the battery. The "dot" printing is shown at Fig. 23.

In the other form of "Printer" the Morse code is printed in "dot" and "dash" characters, the groups and sequence of groups forming the letters and words exactly corresponding with the dot and dash perforations in the Jacquard ribbon. Fig. 24 is the automatic printing upon this system from the perforated ribbon shown at Fig. 20. Capillary attraction is here again made use of, only in a different manner. A small inking disc of metal mounted upon a delicately poised axle capable of a slight angular oscillation in a lateral direction, according as it is influenced by the to-and-fro motion of a permanent mag-

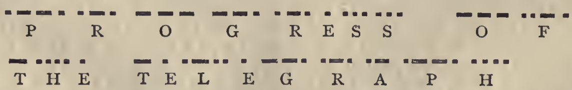

FIG. 24.—An "electric loom," or automatic telegraph printed message from the perforated paper ribbon (Fig. 20.)

netic armature when acted upon by the alternate currents passed into the line from the "Transmitter," is made to rotate rapidly by the same mechanical means that advances the paper ribbon. This little rotating inker is placed close to the surface of the paper ribbon, so that on receiving a lateral motion in one direction its edge is pressed against the paper and removed from it by an

* Continued from vol. xi. p. 512.

opposite motion, while in its neutral position it is free from contact. Thus contact with the paper will produce marks, either dot or dash, according as the inking contact is either momentary or of a sensible duration; the contrary movement producing the spacing between the printed marks. Now, as the currents from the Jacquard ribbon (Fig. 20) are passed at equal intervals and in alternate directions, the spacings between the signals will be automatically regular; the "dash" being the effect of the retention of the magnetic armature acting on the inking disc for double the time of the "dot", by reason of the grouping of the perforations to form the "dash," giving a longer duration without a reversal of the current being passed into the circuit. The arrangement for supplying ink to the little revolving inking disc is simple and effective. A metal wheel, having its edge cut into a V shape, is kept revolving in a dish of ink, and by capillary attraction this V groove is kept constantly filled with ink, and thus the periphery of the little inking disc which revolves in this groove of ink is without any rubbing friction kept constantly supplied with the proper amount of ink to continuously record the rapid motion of the armature as the currents flow from the transmitter into the wire. It is by these very simple means that Wheatstone has produced his high-speed printer, at once an accurate recorder and a telegraphic necessity in these days of special press-transmissions to the chief commercial centres of the United Kingdom.

In order to realise the great value of the automatic high-speed system upon extended lines of telegraphic transmissions, it is only necessary to compare the speed of the Morse apparatus on lines of a given length with that of the automatic electric Jacquard weaver. With an apparatus combining such celerity of transmission and recording powers, it becomes necessary to adopt a special system for the despatch and receipt of intelligence; to economise manual labour, and utilise the capacity of the wire to the greatest extent. Messages are therefore passed into the machine for transmission along the wire in groups; that is to say, on a circuit of 300 miles in length, twelve messages will be perforated upon a continuous ribbon and sent through the "transmitter" at the same time, and *vice versâ*. Employing a wire of a capacity known as No. 8 Birmingham wire gauge over this distance, four

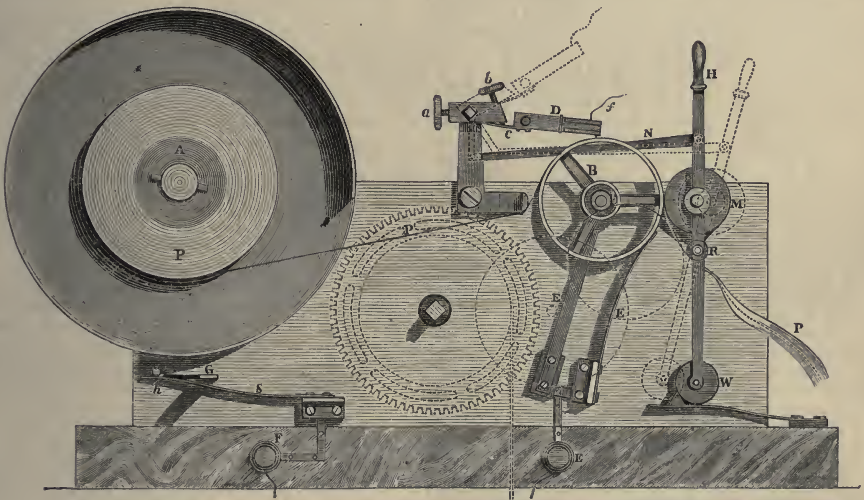

FIG. 25.—Alexander Bain's Automatic Chemical Printing Telegraph, 1846.

distinct groups consisting of twelve messages of thirty words each can be forwarded, and three similar groups received, in an hour; equivalent to eighty-four messages of thirty words each, and with the average of five letters to a word, a total of 12,600 letters, or an average of 210 letters per minute, equivalent to forty-two words per minute, with all the necessary formalities and acknowledgments in addition. Such a speed may be maintained in moderately fine weather, and requires a staff of five clerks at both the receiving and transmitting stations; namely, two for perforating the messages on to the paper ribbon, two for writing or translating, and one for the working of the apparatus in sending acknowledgments and signals for repetitions, &c. When dealing with parliamentary and newspaper despatches, a much higher speed can be obtained, first because there is no necessity for grouping the messages, and secondly because, as a rule, the transmissions are only in one direction, either as wholly received or forwarded messages, which circumstances greatly reduce the initial delay in the transmission. With a No. 4 wire gauge between Aberdeen and London, forty words may be reached, and with a No. 6 wire between Edinburgh and London fifty words, between Newcastle-upon-Tyne and London sixty words, and between Glasgow and Liverpool 120 words may be recorded. The shorter the length of the line, the greater the speed obtained. A very rapid form of a chemical automatic printing telegraph has been designed in America, based upon Alexander Bain's chemical automatic printer, 1846. This American chemical automatic machine has sent and printed, under favourable conditions, intelligence between Washington and New York, a distance of 282 miles, at a speed of 1,050 words or about 5,250 letters per minute, at which rate the apparatus required ten perforators, thirteen copyists, and two instrument-operators to keep the circuit supplied and the transmissions transcribed for general circulation. How far such a speed can be profitably employed for telegraphic purposes remains to be developed. It is quite possible to transmit intelligence beyond a profitable speed, for, irrespective of the difficulty of always commanding a sufficient amount of intelligence to keep the apparatus fully employed, the vast staff of manipulators necessary to ensure the preparation of the Jacquard ribbon, and translation of the symbolic

code into language, must always form a very important element in the commercial value of all high-speed arrangements, when the speed is beyond that of the public requirements of the circuit.

Alexander Bain's chemical printing telegraph, invented in 1846, of which this American automatic machine is only a modernised adaptation, is shown at Fig. 25. It combined methods of arranging, transmitting, and receiving electrical telegraph communications, in which mechanically-composed communications were transmitted through electric circuits, and received by chemically prepared surfaces, both apparatus being kept in motion by mechanical means, without the aid of magnets. The apparatus consisted of a frame containing a driving power by which a rotatory motion was imparted to the metal drum B, placed in connection with the earth by means of the contact springs E E. The paper strip P P, chemically prepared by being immersed in a solution of sulphuric acid and prussiate of potass to receive the sequence of currents transmitted through the wire from the "transmitter," is wound upon the drum A, and is drawn forward over the revolving earth contact B at a uniform speed by reason of the pressure of the break roller M, which may, whenever the paper is not required to advance, be withdrawn by the lever H working on the centre R, and kept in position either way by the action of the spring roller W. An insulated metallic style D, in connection with the line wire *f*, and furnished with the necessary screw adjustments *a*, *b*, *c*, is arranged to press uniformly upon the chemically-prepared paper as it passes over the earth drum B. The style D can also be removed from pressing contact with the paper ribbon when required, as indicated by the dotted outline. When therefore the style D is passing over the surface of the prepared paper, and electric currents are passed through the line wire *f* from the distant station, the electric circuit will be completed through the paper ribbon P, and the metallic drum B, with the earth E, and in the passage of the current, the iron in the chemical solution is decomposed and a dark blue mark becomes visible upon the paper corresponding in length to the duration of the current; so that if the Jacquard ribbon at the distant station is perforated into the necessary length of holes to represent the sequences of dots and dashes in the Morse code, to form letters and words, the chemical decomposition from the style D will be an accurate replica of the distant message in the "dot" and "dash" symbols. It was thus that in 1846 Alexander Bain, the clever and ingenious Edinburgh watchmaker, originated a system of electric automatic chemical Jacquard printing, which even at the present day is scarcely understood, and which in all probability is left to American skill to develop. Its extreme simplicity and wonderful chemical sensibility speak volumes in its favour, provided, as has been already observed, such extreme velocities can be profitably worked in this small planet of ours.

(*To be continued.*)

RECENT FRENCH MATHEMATICAL PUBLICATIONS

M. CHASLES is reprinting a new edition of his celebrated work, "Aperçu Historique:" the first part has been already issued. The learned geometer has made no alteration in the book, which was written many years ago and long before he had been led to assert frivolous claims in favour of Pascal, and no allusion is made to the Newton forgeries. The whole work will cost no more than 20*s*., only one-fourth of the selling price of the old edition, which has for some time been very scarce.

There has been in France a revival of interest in the subject of imaginary quantities. Thus, a translation by Laisant of Bellavitis's "Calcul des Equipollences" has been published lately. It is regarded by Bellavitis himself as a system of quaternions in one plane, and thus is somewhat analogous to the efforts made in England to popularise the great Hamilton's theories. But it is only a partial effort, as Bellavitis's results do not admit of being generalised so as to apply to solid geometry.

M. Hoüel, whose name is connected with the publication of a series of useful tables, will very likely be more successful in this respect, as he is preparing a "Theory of Quaternions."

The same mathematician has edited a reprint of a work on the "Geometrical Representation of Imaginary Quantities," originally published in 1806 by Argand. One of his objects appears to have been to defend the rights of his illustrious countryman. But they are not so disregarded in England as the author seems to suppose.

The third and concluding part of the new edition of Briot and Bouquet's "Theory of Elliptic Functions" has appeared. It is quite a new book, though professing to be a second edition of the small octavo volume which became rapidly so popular amongst mathematicians.

M. Paul de Saint Robert has published a third and concluding volume of his interesting "Memoirs," several of which were published in English in the *Philosophical Magazine*. Amongst these valuable papers, which are here reprinted, we must not neglect to notice the "New formulæ for determining the altitude from barometric observations." These formulæ embody the results of the observations taken by Mr. James Glaisher in some of his aëronautical ascents. M. Saint Robert in this way improves the well-known Laplace's formulæ, which were based only on the Ramont's observations taken in the Pyrenean ranges; and takes into account the carefully observed facts which had been neglected in England.

NOTES

THE Committee on the Loan Exhibition of Scientific Apparatus met in the Science Schools at the South Kensington Museum yesterday. It has been determined to postpone the exhibition till March 1876, and from the strength of the Committee appointed and the interest taken in the scheme by scientific societies, we may expect the collection to be unique.

IT will be of interest to geologists to know that Capt. Feilden, R.A., the naturalist of the senior ship of the Arctic Expedition, in addition to making the observations on the birds of Northern Europe, Malta, India, China, and North America, which will be found scattered through the pages of the "Zoologist" and quoted by Prof. Newton and Messrs. Sharpe and Dresser in various works, has given much attention to the palæontology of many of these countries, especially to the Miocenes of Malta and the Faroe islands, and the Mastodon beds of South Carolina. By permission of Prof. Ramsay, V.P.R.S., the Director-General of H.M. Geological Survey, Capt. Feilden has also recently been shown the method employed in carrying out geological field-work by that Survey, by one of its staff, Mr. De Rance.

THE French Academy of Sciences, at its sitting on Monday last, received the report of M. Fleuriais, the head of the Transit of Venus Expedition to Pekin. The observations were very satisfactory indeed, the four contacts having been photographed with complete success. The weather was very boisterous all the day long, but at the four important moments the observers were favoured by a total absence of clouds. They succeeded in executing a map of Pekin, in spite of the obstacles placed in their way by the natives. The dimensions are 8,000 metres by 7,000, and the length of the walls is 33 kilometres. The instruments set up by the missionaries last century are in perfect

order. The instruments sent by the Academy to China are to remain there, and perhaps a permanent observatory may be established.

Prof. James Dewar, in resigning his post of Chemist to the Highland Agricultural Society, on his appointment to the Jacksonian Chair, Cambridge, has told that Society some wholesome truths, which we hope they will take to heart. Mr. Dewar writes :—"After what has occurred, it will hardly be necessary for me to say anything about what might have been had the chemical department been rearranged in the way I naturally anticipated after the death of Dr. Anderson. You are aware I intended prosecuting investigations in vegetable physiology, had the proper means been placed at my disposal ; and the desire to do so was the main reason of my leaving the University. As it seems, however, the opinion of a portion of the Society that an agricultural chemist (so-called by the uninitiated, because his business is chemical analyses and the manipulating of the farming interests) rather than a scientific chemist would be best qualified to discharge the duties of the office of chemist, I have considered it my duty to accept the Cambridge Professorship as the best means of getting out of a false position. I still trust, however, the Society will ultimately see that this office of chemist will never be properly filled except by one thoroughly trained in scientific research, and this, the making him a real agricultural chemist, will depend on the means placed at his disposal for applying his scientific knowledge to agriculture."

We are glad to see that the University of Glasgow is doing what it can to promote experimental investigation among its students ; for this purpose the following two prizes are offered :— 1. In Natural Philosophy, the Cleland Gold Medal, for the best "Experimental Determination of Magnetic Moments in Absolute Measure." All students of the Natural Philosophy Class in Session 1874–75, or Session 1875–76, may be competitors. 2. The Watt Prizes of 10*l*. for the best "Numerical, Graphic, and Experimental Illustrations of Fourier's Solutions of Problems in Thermal Conduction." Cooling of a cylinder to be worked out *numerically* in one or more cases : cooling of a globe may be illustrated *experimentally* in one or more cases. All matriculated students of the University in Session 1875–76, who have finished, or who on the 1st day of May, 1876, shall finish a regular course of Languages and Philosophy, may be competitors. Two or more competitors for the prize may work together and give in a joint essay ; and two prizes will be given in case of sufficient merit. The Physical Laboratory of the University will afford the requisite experimental means for candidates for the Watt and Cleland Prizes. When will Oxford and Cambridge follow such a good example ?

It is with great regret that we record the death, in his fifty-fourth year, of Admiral Sherard Osborn, C.B., F.R.S., which took place suddenly on Thursday night last. Admiral Osborn's name is well known in connection with Arctic exploration, and he was to have read a paper last Monday on the Arctic Expedition before the Royal Geographical Society. He was born April 25, 1822, entered the navy in 1837, and served in the East Indies and in China. He obtained his commission as lieutenant in 1846, and three years later was selected as a volunteer for the Arctic Expedition, under Capt. H. T. Austen, sent in search of Sir John Franklin, being appointed to command the *Pioneer*. He afterwards served with distinction during the Russian war, in China, and in Mexico. In 1864 Capt. Osborn was appointed to the command of the turret-ship *Royal Sovereign*, and was afterwards for several years managing director of the Great Indian Peninsular Railway at Bombay. Admiral Osborn naturally took a keen interest in the Arctic Expedition which is so soon to leave our shores.

The following naturalists have been elected foreign members of the Linnean Society of London, viz. : Alexander Agassiz, H. E. Baillon, Ferdinand Cohn, M.D., A. de Quatrefages, and F. Parlatore.

Dr. G. J. Allman, F.R.S., has been elected Examiner in Zoology, and Dr. M. T. Masters, F.R.S., Examiner in Botany to the University of London.

An outline of the lectures on the Invertebrata being delivered at Edinburgh University by Prof. Huxley is being published in the *Medical Times and Gazette ;* the first instalment appeared in last Saturday's number.

Our readers are familiar with the name of the Penikese School of Zoology in the United States, and last week we gave the programme of a similar institution for the practical study of Geology. The faculty of Harvard College are, we believe, arranging for similar schools for other branches of scientific instruction, and have announced three separate courses, besides the one on Geology :—One of Chemistry, under Prof. J. P. Cook, to be held at Cambridge. The second is a course in Phenogamic Botany, to be given in the Botanical Laboratory at Cambridge, by Prof. Goodale. The Botanical Garden and Herbarium will furnish material for instruction in Structural and Systematic Botany. All necessary appliances, including dissecting and compound microscopes, will be furnished by the instructor. The third course is that of Cryptogamic Botany, under Prof. W. G. Farlow. This course will be held at some point on the sea-shore, possibly Provincetown or other suitable locality, and in this respect will correspond to the plan of the summer school of zoology at Penikese. Twelve lectures will be devoted to the Algæ and six to the Fungi. A laboratory will be established, and excursions will be made throughout the course by the students in company with Prof. Farlow.

From Baron Mueller, Government Botanist of Victoria, Australia, we have received his last report of the progress and condition of botany in that colony. From a scientific point of view, and equally in regard to the advance of applied botany, it contains many interesting particulars. The learned writer, who has done so much to promote the development of the vegetable resources of Australia, laments the withdrawal of the working votes of his department, and his removal from the directorship of the Botanic Garden, as he is thereby deprived of the means of conducting his researches. We glean the following notes from this report. The vegetation (exclusive of some of the lower cryptogams) of the whole of Australia is estimated at 11,000 species. The number of grasses is about 250 species. Numerous experiments have been made to ascertain the quality and practical working of various fibres, oils, tars, acetic acid, gums, resins, starch, potash, paper materials, dyes, &c., obtained from native and introduced plants, a complete list of which is appended to the report. In some experiments on rabbits with the tubers of *Burchardia umbellata* and *Anguillaria australis*, it was ascertained that although belonging to a doubtful family, they contain no noxious principle. In the search for jalap in the tubers of indigenous terrestrial orchids, the common *Microtis porrifolia* gave the best and highly satisfactory results. In drying, the roots of this species evolve a slight violet odour, and ten grains of the dry powder produces one ounce of good pale mucilage, free from bitterness. The tubers of *Thelymitra aristata*, although still richer in mucilage, are slightly bitter and of a brownish tinge. Very much has been effected in the distribution of the seeds of the gum trees (*Eucalyptus*), of which there are 140 species in Australia, and intesting the qualities of the numerous products of these valuable trees. In a trip to the forest regions of the Upper Yarra last year, Baron Mueller measured some trees of *Eucalyptus amygdalina*, var. *regnans*, which were approximately 400 feet in height. The magnificent grass *Festuca dives* was found in the same region growing to a height of 17 feet on the

borders of rivulets. For educational purposes in the colonial schools, 100 sets of native plants have been dried and mounted, each set containing fifty species. Since the publication of the last report about fifty new genera have been added to the flora of Australia, including many of great interest in phyto-geography. Thus the genera *Corynocarpus* and *Carmichaelia*, previously only known from New Zealand, have been discovered in Australia. A species of *Ilex* (holly) has also been found, and an elm belonging to the section *Microptelea*. About fifteen of the genera are absolutely new to science.

THE excellent collection of Madeira plants formed by the late Rev. Mr. Lowe, who, with Mrs. Lowe, was lost last year in the wreck of the *Liberia*, was deposited in the Herbarium at Kew some months since, and is, we understand, to be divided between the British Museum and the establishment named, the latter taking the *uniques*. It is fortunate that so valuable a collection has become public property, as it contains the types of the lamented gentleman's new species, and specimens of many things that are now exceedingly rare in the islands. In private hands it might have been neglected, and certainly would have been inaccessible to most botanists.

IN the appendix to the United States Coast Survey Report for 1872, now in the press, is a report by Mr. W. H. Dall on the tides, currents, and meteorology of the Eastern Aleutian region and the North-east Pacific, accompanied by explanatory diagrams. Mr. Dall's observations on the oceanic currents, which are here tabulated and discussed up to the date of the report, are of special interest as being the first series undertaken with a direct view to the solution of the problems in question, and result in the proof of the existence of a reflexed northerly arm of the great easterly North Pacific current, denominated by him the Alaska current, which had previously been surmised from isolated observations and theoretical considerations. Mr. Dall has been enabled to determine the rate and dimensions of several portions of this current, and maximum, minimum, and mean annual temperature. The existence of definite oceanic currents in the eastern half of Behring Sea is shown to be very doubtful. Some important generalisations on the relations of the Pacific and Behring Sea tides to each other are made, and the peculiarities of the compound tides of this region are graphically indicated by diagrams in a new method, original with the author, and possessing some interest for those studying these problems. The report is accompanied by numerous hydrographic memoranda and tables of meteorological, current, and tidal observations.

THE figure to the letter in last week's NATURE (p. 7), signed X, "On the rôle of feet in the struggle for existence," does not quite illustrate the author's meaning. He intended to draw the same footprint in both cases, but in the case shown in the cut on the left, each footprint should be advanced straight forward in the line of the previous one, while in the other it should be advanced obliquely, leaving a large part of the outline of the previous one clearly marked.

A MEETING was held on Monday last in the theatre of the Royal Institution, Mr. A. J. Mundella, M.P., in the chair, for the purpose of considering the best mode of extending to London the benefits of the Cambridge University Extension Scheme, at which the following gentlemen, among others, were present :—Sir J. Lubbock, Bart., M.P., Dr. L. Playfair, M.P., Dr. W. B. Carpenter, F.R.S., Dr. J. H. Gladstone, F.R.S., Sir H. Cole, C.B., Mr. S. Morley, M.P., Prof. Fawcett, M.P., Mr. T. Hughes, Q.C., Hon. G. Brodrick, Rev. W. Rogers, Mr. H. C. Sorby, F.R.S., and Mr. Jas. Stuart. After Mr. Stuart and Mr. Sorby had explained the object of the meeting, the following resolution was carried :—"That this meeting, having heard Mr. Stuart's statement, considers it desirable to introduce into London the Cambridge University Extension Scheme." A provisional committee was appointed to carry out the objects of the meeting, consisting of Mr. S. Morley, Mr. Mundella, Mr. Jas. Stuart, Rev. W. Rogers, Mr. T. Hughes, Mr. R. N. Phillips, Dr. Carpenter, Mr. W. L. Birkbeck, Mr. H. C. Sorby, and Mr. G. M. Norris.

THE regular annual meeting of the U.S. National Academy of Science took place at the Smithsonian Institution in Washington on the 20th of April, and continued three days. The attendance was about the same as usual, there being some twenty-five members present out of the seventy-five. Numerous papers of much scientific interest were brought forward. In accordance with the rules of the Academy, five new members were elected. These are: Prof. R. E. Rogers, Professor of Chemistry of the University of Pennsylvania; Prof. Asaph Hall, one of the astronomers at the Washington Observatory; Prof. Alpheus Hyatt, curator of the Natural History Society of Boston; Prof. Joseph Le Conte, of the University of California; and Mr. Lewis H. Morgan, of Rochester. All these gentlemen are eminent in their respective branches of science, and constitute a valuable addition to the membership of the Academy, which now embraces about eighty individuals, selected from the representative men of science throughout the United States. The only loss which the Academy has experienced by death during the year is, as stated by the president, that of Prof. Jeffries Wyman.

SIR CHARLES REED, as a member of the Gresham Committee, writes to the *Times*, giving the arrangements which have been made for the future conduct of the Gresham Lectures. The lectures are not in future to be delivered in the Latin tongue. The times of delivery are to be fixed, not by the lecturers, but by the Committee. The lecturers are required to deliver their own lectures, and the nomination of a substitute is allowed only in case of illness. The appointment of the lecturer is for one year, securing to the Committee an opportunity of annual revision. It will be seen that the Committee have taken a step in the right direction, and we hope that it is only the first step to a radical reform.

A scientific Society has been formed in Bedford, under the title of the Bedfordshire Natural History Society and Field Club.

IN reference to Mr. Fordham's letter in last week's NATURE, in which he states that in his part of the country the cowslip is very abundant but the primrose is not found, Mr. J. J. Murphy asks, what part of the country Mr. Fordham means? The opposite is true at Dunmurry, Co. Antrim, where there is plenty of primroses, but few if any cowslips.

WE are glad to see that at the great International Exhibition to be opened at Philadelphia next year, a Department (VII.) is to be devoted to "Apparatus and Methods for the Increase and Diffusion of Knowledge." The following are the groups into which the department is divided :—Educational apparatus and methods. Typographic aids to the preservation and dissemination of knowledge, books, periodicals, newspapers. Charts, maps, and graphic representations. Telegraphic instruments and methods. Instruments of precision, and apparatus of physical research, experiment, and illustration. Meteorological instruments and apparatus. Mechanical calculation—indicating and registering apparatus, other than meteorological. Weights, weighing, and meteorological apparatus—measures and coins. Chronometric apparatus—time-keepers of all kinds, watches, clocks, &c. Musical instruments and acoustic apparatus. Under Department X. also there are two groups which might be classed along with these :—Education: illustration of the various systems and accessories of education, from the infant school to the University, including special schools of science and art, libraries, &c. Institutions, Societies, and Organisations having for their object

the Promotion of Science: illustrations of the rise, progress, and results of the various organisations for the promotion of science; models, drawings, descriptions, and statistics.

MR. STANFORD has just published a North Polar map, superior in most respects to anything we have seen. It embraces a circle of forty degrees from the pole, thus including the whole of England. It exhibits faithfully all the circumpolar lands hitherto discovered, and in bold red letters shows the points reached by all the most important discoverers, with the date of discovery, from Sebastian Cabot down to Payer and Weyprecht; even the spot where it is hoped that H.M.S. *Discovery* will winter is indicated. By means of dark and light blue, the usual limits of the ice and open water are clearly shown, and the whole execution of the map reflects the greatest credit on Mr. Stanford's establishment.

WE have seen an ingenious scientific apparatus which entirely obviates the use of matches or tapers, and does away with the attendant danger in lighting gas. It consists of a small bichromate of potash battery, the zinc plate of which is so arranged that by the pressure of the finger it can be immersed in the exciting fluid and put the battery in action. Rising from the top of the battery is a light brass stem, like a taper-holder, but in the form of a swan's neck, terminating in a little bell, within which the two "poles" of the battery are united by a spiral of platinum wire; this wire, when the battery is put in action by the immersion of the zinc plate, becomes white hot, and will instantly ignite the gas if held over the open burner. The name which the maker, Mr. Horatio Yeates, has given to this happy contrivance is the "Galvano-Pyreon, or Voltaic Gas-lighter."

M. ELIE DE BEAUMONT left a library containing a number of valuable scientific books, which his nephew and heir has presented to the Geological Survey of France, of which his uncle was Director. The grant includes more than 2,000 volumes relating to geology, and 600 maps.

WE formerly mentioned that the widow of the late General Poncelet founded a few years ago a prize to be awarded by the Institute. It was a handsome sum of money to be given every two or three years to the author of the best essay on Mechanics. Last week Madame Poncelet sent to the Academy a large number of copies of the *Œuvres Complètes* of her husband, which were completed only last month, with the request that each successful competitor for the Poncelet Prize should be presented with a copy. But as the stock would be exhausted in the course of five or six centuries, the careful widow has created a special accumulating fund providing for a new edition in the year 2600 A.D.

THE Paris Acclimatisation Society held its anniversary meeting on the 6th of May, under the presidency of M. Drouyn de Lhuys. M. Pichot gave a long and interesting address on acclimatisation in Egypt under the Pharaohs. Many prizes were awarded for practical results obtained in the way of introducing new kinds of animals into France. One of these was given by M. Joseph Cornely, for having succeeded in the multiplication of the kangaroos left in a state of liberty.

THE additions to the Zoological Society's Gardens during the past week include a Guinea Baboon (*Cynocephalus sphinx*) from West Africa, presented by Mr. Lionel Hart; a Yellow-shouldered Amazon (*Chrysotis ochroptera*) from South America, presented by Miss M. Sutherland; a Molucca Deer (*Cervus moluccensis*), a Pampas Deer (*Cervus campestris*), born in the Gardens; two Chinese Jay-Thrushes (*Garrulax chinensis*) from China, purchased; a Patas Monkey (*Cercopithecus ruber*) from West Africa; a Hairy Tree Porcupine (*Cercolabes rupestris*), a Rock Cavy (*Cerodon rupestris*) from Brazil, deposited.

NATURAL HISTORY OF KERGUELEN'S ISLAND *

IT is difficult, owing to the inexactness of the charts, to inform you of the positions of the Astronomical Stations in whose neighbourhood I have been able to work in this island. The German station is in Betsy Cove, the American at Molloy Point, Royal Sound. The English stations also are in this Sound, the second being situated about three miles N. by W. of Swain's Haulover. The first English station is between these last two on the main land, six or seven miles N.W. of Three Island Harbour, in what will be called Observatory Bay. Two days before the Transit of Venus a party under Lieut. Goodridge, R.N., was detached from the first English station to observe the transit from a position which he selected near the base of Thumb Peak. I have not yet been able to visit Betsy Cove.

Observatory Bay is one of the minor inlets of a peninsula comprised between two narrow arms of the sea. One of these runs up from the Sound, along the western flank of the hills adjacent to Mount Crozier, several miles, and terminates at a distance of three or four hours to the north of us, and about four miles from the inlet near Vulcan Cove. The other arm, opening nine or ten miles away to the southward, proceeds in a north-easterly direction to within three or four miles of the former, and no great distance from Foundry Branch.

Besides the inlets of the sea, numerous freshwater lakes present obstacles to inland travelling. Some in this neighbourhood are two or three miles in length, but in general they are not more than a mile long. They are usually shallow, and appear to be uninhabited by fish. The bogs and streams in this vicinity are not impassable, but can be traversed with ease if ordinary care be taken.

The most salient features of the landscape are the basaltic hills, with irregular terraces of rock on their sides, and broken cliffs at their summits. In lieu of grass, their slopes are clothed with banks and boulder-like clumps of *Azorella selago*, excepting where rich damp loam affords a soil suitable for the *Acæna* and the *Pringlea*. Here and there a fern (*Lomaria*) and grass (*Festuca*) grow in the interspaces of the other plants.

The climate of Royal Sound is far warmer and drier than we were led to expect it would be. In November the weather was very pleasant; since then it has deteriorated, though the snow has not again covered the ground as it did when we first arrived. Probably the previous accounts of its meteorology were based upon observations taken in parts of the island where bad weather prevails; or it may be that the condition of the country in winter has been presumed to be constant throughout the year. In one respect we were rightly informed; for usually when there is no breeze there is a gale. A calm day is an exceptional event. Meteorological observations are being taken in Observatory Bay on board the *Volage* and by the sappers on shore.

Corresponding with the unlooked-for superiority in climate, a difference is noticeable in the vegetation of this part of the island. Some plants which occur at both extremities of the country display in Royal Sound marks of luxuriance. For instance, *Pringlea antiscorbutica*, which is elsewhere apetalous, here in sheltered places frequently develops petals; some flowers in the same inflorescence possessing one petal only, others having two, three, or four. And the petals are not always of a pale greenish colour, but occasionally are tinged with purple. Again, *Lomaria alpina*, which is mentioned in the flora as rare in the neighbourhood of Christmas Harbour, is excessively common and very finely grown here. There are also more species of flowering plants and of the higher orders of Cryptogamia here than were found by the Antarctic Expedition at the north of the island. But there are fewer species of mosses, lichens, and algæ. Their paucity, in comparison with those of the other district, is probably due to the nature of the rocks on land, and to the seclusion of the bay from the open sea. The additions to the flora are for the most part Falkland Islands species.

In speaking of the climate, it may be mentioned that the plants of Kerguelen's Island are not (as was supposed) in flower throughout the year; but probably some of them do not cease flowering until late in the winter. When we first arrived in Royal Sound the ground was covered with snow, and scarcely

* "First Report of the Naturalist attached to the Transit of Venus Expedition to Kerguelen's Island, December 1874." By the Rev. E. A. Eaton. Communicated by the President. A letter to the Secretary of the Royal Society, dated Royal Sound, Kerguelen's Island, 31st December, 1874. Read April 8.

anything had begun to come out. The *Pringlea* was far advanced in bud, barely commencing to blossom. The *Acæna* was just beginning to burst into leaf. About the first week in November *Festuca Cookii* came out, and a few days later *Azorella selago*. The young fronds of the ferns were just about to unroll. In the third week of the same month *Montia fontana* and *Acæna affinis* were in flower in a sheltered spot, and *Leptinella plumosa* was first found in blossom. *Galium antarcticum* appeared about the same date. A week later, *Ranunculus hydrophilus* and a *Festuca* (*purpurascens?*) were out, and *Lycopodium clavatum* was sprouting. By the middle of the month *Triodia* and *Lyallia kerguelensis* and also *Ranunculus crassipes* were in flower; the *Pringlea* was everywhere past flowering (excepting upon the mountains), and *Aira antarctica* began to shoot forth its panicles. Before the end of the month a *Carex* came out; but *Bulliarda* and other plants delayed still.

A few species of Mammals have been introduced into the island. Mice (evidently *Mus musculus*, L.) are common along the coast, and have been found by us in various places. The rabbits, transported by order of the Admiralty from the convict settlement in Table Bay, have been landed by H.M.S. *Volage* in Royal Sound. They share with the birds holes of the petrels, and are (it is almost superfluous to mention) propagating freely. Their favourite food is the *Acæna;* but they occasionally eat *Pringlea* leaves and gnaw away the green surface of *Azorella*. In the Crozettes, whose climate and flora are said to resemble those of this island, rabbits have become extremely abundant, and so rank and coarse that the sealers will not eat them. Goats are increasing in numbers on the leeward side of the main land.

Whales and porpoises occasionally enter the Sound. Old skulls of the latter, wanting the lower jaw, are cast up here and there on the beaches.

Up to the present time I have captured only two species of seals—a female sea leopard and two males of a Platyrhine Seal. The other kinds frequent the more open parts of the coast and islands.

Twenty-two species of birds, at the fewest, perhaps twenty-three, frequent Royal Sound, viz., a *Chionis*, a Cormorant, a Teal, a Tern, a Gull, a Skua, eleven (perhaps twelve) Petrels, two Albatrosses, and three (perhaps four) Penguins. Of these, I have procured eggs of the first six; also of six Petrels, one Albatross, and two Penguins. The *Thalassidromæ* are preparing for laying.

Fish are rather scarce in Observatory Bay. Only three species have hitherto occurred to us, two of which are common under stones at low water. The remains of a *Raia* have also been picked up on one of the islands by an officer of the *Volage*, but hardly sufficient is left to enable the species to be determined. It is allied to *R. clavata* and *R. radiata*.

The entomology of the island is very interesting. Most of the larger insects seem to be incapable of flight. I have found representatives of the orders Lepidoptera, Diptera, Coleoptera, and Colembola.

The Lepidoptera comprise a species of the *Noctuina* (as I suppose) and one of the *Tineina*. Of the first I have not yet reared the imago; the larva is a moss eater and subterranean: the adult is probably as large as an *Agrotis* of medium size. The species of *Tineina* is probably one of the *Gelechidæ*, judging from the form of the palpi. Its larva feeds on young shoots of *Festucæ*, and sometimes spins a silken cocoon for the pupa. The imago, of which the sexes are alike, has acute and very abbreviated wings, and the posterior pair extremely minute. In repose the antennæ are widely separated, and almost divaricate. When the sun shines the adult is active, and, if alarmed, jumps to a distance of two or three inches at a time. During its passage through the air the wings are vibrated.

The Diptera are represented by species of the Tipulidæ and Muscidæ. There are three of the former family. One of them is a small species of the Cecidomyidæ, which is abundant in mossy places, and presents no marked peculiarity. Another seems to be a degraded member of the Tipulidæ. The antennæ have six joints, the palpi two; the wings are ligulate and very minute. It possesses halteres, and the female has the ovipositor enclosed in an exposed sheath. Although it is unable to fly, it lives upon rocks in the sea, which are covered at high water, and there it deposits its eggs in tufts of *Enteromorpha*. The third species has full-sized wings: it was caught in the house. The indigenous Muscidæ are very sluggish in their movements, and are incapable of flight. Four species are common about here. One of them is abundant on *Pringlea*, crawling over the leaves. When it is approached it feigns to be dead, and, tucking up its legs, drops down into the axils of the leaves; or, if it happens to be upon a plane surface, one need only look at it closely, and it throws itself promptly upon its back and remains motionless until the threatened danger is over, when it gradually ventures to move its limbs and struggle to regain its footing. Its wings are represented by minute gemmules, and it possesses halteres. The ovipositor is extended, its apical joint alone being retracted. The penis is porrected beneath the abdomen, where it fits into a notch at the apex of the penultimate segment. The larva feeds on decaying vegetable matter. Another species occurs on dead birds and animals, as well as beneath stones near the highest tide-mark. It is completely destitute of even the vestiges of wings and halteres. The sexual organs are concealed. It and the preceding species are rather smooth. A third species, slightly hairy, is common among tide refuse and on the adjacent rocks, which are coated with stunted *Enteromorpha*, on which plant, *inter alia*, the larva feeds. It has very small triangular rudiments of wings, slightly emarginate near the apex of the costa, and possesses halteres. The sexual organs are not exposed. The fourth species occurs amongst grass growing along the shore, and also in Shag rookeries. Its linear and very narrow wings are almost as long as the abdomen. It can jump, but cannot fly. The sexual organs are retracted.

A *Pulex* is parasitic upon *Halidroma*, and one (possibly the same species) on *Diomedea fuliginosa*.

Coleoptera are not uncommon. The larger species seem to have their elytra soldered together. There is a small species of the Brachyelytra.

Several species of *Nirmiidæ* have been obtained.

Two *Poduræ* (one black, the other white) are plentiful.

There appear to be few species of Spiders, though individuals are numerous. Penguins and some of the other birds are infested with Ticks. The remaining Arachnida are related to *Cribates*.

The Crustacea, Annelida, Mollusca, and Echinodermata in this part of the island have probably been collected by the *Challenger* more extensively than I have been able to do; therefore I need not particularise further about them than to state that Entomostraca abound in the lakes; an earthworm is common, and a land-snail is very plentiful amongst the rocks on the hills. This last appears to appreciate comparative heat, for specimens obtained in an exposed place during the frosty weather were assembled together for warmth, under the drip of an icicle.

In Observatory Bay Cœlenterata are not numerous. One or two species of Actiniidæ on the rocks and Macrocystis roots, and an Ilyanthid in mud, are the only Actinozoa I have met with. The Hydrozoa similarly have afforded only three species—a Corynid, a Campanularian, and a *Sertularella*.

There are several Sponges.

With the exception of *Limosella aquatica*, and perhaps *Agrostis antarctica*, I have obtained all the flowering plants and ferns given in the "Flora Antarctica" as indigenous to the island. Besides these, *Ranunculus hydrophilus* and another species, a *Carex*, a *Festuca* (probably *F. purpurascens*, but I have no work containing descriptions of the flowering plants), *Polypodium vulgare*, a fern allied to *Polypodium*, and *Cystopteris fragilis* have occurred to me. There is also a plant which appears to belong to the Juncaceæ. *Lycopodium clavatum* and *L. selago* are common about here. None of the Mosses, Hepaticæ, or Lichens have been worked out as yet; but amongst them are one or two species of *Cladonia*, and some examples of *Lecanora paleacea*. Fungi are represented by *Agaricus* (*Psalliota*) *arvensis*, *Coprinus atramentarius*, and a peculiar parasite on *Azorella*, which grows out from the rosettes in the form of a clear jelly, which becomes changed into a firm yellowish substance of indefinite form. There are also some *Sphæriacei* on grass and dead stems of plants. At present few additions have been made to the marine flora. The larger Algæ in Royal Sound are usually not cast upon the shore by the waves, and I have almost been entirely dependent upon grapples thrown from the rocks for specimens of the more delicate forms. *Polysiphonia Sulivanæ* and *Rhytiphlœa Gomardii* are amongst the novelties. A large number of zoological and botanical specimens have been lost through my inability to attend to them in time without assistance. This has principally affected the number of duplicates; but in one instance it has led to the loss of a species—one of the Petrels, which was the commonest bird about here when we first arrived. Fortunately it is a well-known species.

The 1st of March is announced as the approximate date of our sailing from Kerguelen's Island. Five weeks later I hope to

arrive at the Cape and to forward to you such of the specimens collected as require only ordinary care in their transmission. The more fragile things are likely to reach you in better condition if I keep them until my return to England, than they would if they were sent with the others.

SCIENTIFIC SERIALS

Journal de Physique théorique et appliquée, Feb. 1875.—This number contains several papers reprinted from other serials, and the following original ones :—On the spectra of yttrium, erbium, didymium, and lanthanum, by Prof. R. Thalèn. On account of the difficulty to obtain the compounds of these metals in a pure state, considerable doubt has hitherto existed, whether certain lines that always appeared in the spectra of yttrium and ertium and in those of didymium and lanthanum belonged to the first or second metal in the pair; the state of these questions in 1868 was, that there were twelve lines which always appeared when yttrium or erbium were examined, and sixteen lines in the case of didymium and lanthanum. Prof. Thalèn succeeded in obtaining sufficient quantities of compounds of each of the metals, from M. Cleve, Professor of Chemistry at the Upsala University, and these were of undoubted purity. He was thus enabled to study their spectra most accurately, and the following table shows the number of lines found in former and in the recent researches :—

Metal.	Number of lines. 1868.		1873.
Yttrium	70	+ 12 uncertain	106
Erbium	10		83
Didymium	6	+ 16 ,,	209
Lanthanum	49		188

It was found that the twelve uncertain lines that always appeared with yttrium or erbium belong to yttrium only; in the same way the sixteen uncertain ones in the second case belong only to the lanthanum spectrum. Prof. Thalèn gives a detailed map of the spectra in question.—Researches on the induction sparks and electro-magnets; their application to electro-chronographs, by M. Marcel Deprez.—On analogies in the evolution of gases from their over-saturated solutions, and the decomposition of certain explosive substances, by M. D. Gernez.—On the preservation of energy in electric currents, by M. E. Bouty.—On the transformation of static into dynamic electricity, by M. E. Bichat.

Der Zoologische Garten.—In the January number, the first article is a description of the new Zoological Gardens at Frankfort, by the director, Dr. Max Schmidt, illustrated by a coloured plan. J. von Fischer gives an account of the habits of *Herpestes galera* as observed in confinement. E. Buck figures and describes an apparatus for producing currents in the water of aquaria; it may be worked either by a miniature steam-engine or by clockwork. H. Schacht gives minute details of the breeding habits of the common swallow (*Hirundo rustica*); and A. B. Meyer and K. von Rosenberg both write upon the newly discovered Bird of Paradise (*Diphyllodus Gulielmi III.*, Van Muschenbroek) from Ternate.—In the February number is printed a paper read by Dr. Hermann Müller before the Provincial Society of Westphalia, on the stingless Brazilian Honey-bees of the genus *Melipona*, and the possibility of their acclimatisation in Europe. Dr. J. J. Rein remarks on the distribution of some of the mammals of Japan; and C. Geitel writes on the feeding of small birds in winter in the neighbourhood of human habitations.

Poggendorff's Annalen der Physik und Chemie, 1875, No. 2, contain the following papers :—On the galvanic conducting capacity of melted salts, by F. Braun. The author experimented with twelve different salts, and tabulates his results; the salts were nitrates of potash, soda and silver, carbonates of potash and soda, sulphate of soda, chlorides of potassium, sodium, strontium, zinc and lead, and iodide of potassium.—On a compilation of facts which prove a decrease of volume as a consequence of chemical action in solid bodies, by W. Müller.—On the electric conducting capacity of the chlorides of the alkalies and alkaline earths as well as of nitric acid in aqueous solutions, by F. Kohlrausch and O. Grotrian. This is the last part of the author's interesting communications, and treats of the liquids examined, of the resistances observed, of the conducting capacities in their relation to that of mercury, and of their dependence on temperature; further, of their proportion to the percentage of concentration of liquids, of the co-efficients of temperature, and of the conducting capacity of dilute solutions.—On the theory of galvanometers, by H. Weber.—A reply to Baron Eötvös' remarks on a part of the astronomical undulation-theory by Ed. Ketteler.—Some remarks upon Helmholtz's work on Sound, "Die Lehre von den Tonempfindungen," by Emil v. Quanten; these remarks relate principally to what Helmholtz says on vowels.—A reply to Herr C. Heumann regarding his claim of priority in observing the action of nitrate of silver upon sulphide of copper, by R. Schneider.—On the construction of lightning conductors, by Dr. W. A. Nippoldt. Some remarks by Dr. G. Baumgartner, on Prof. E. Edlund's paper on the nature of electricity.—Description of a very simple apparatus to photograph spectra, by Hermann W. Vogel; this apparatus can even be applied to an ordinary pocket spectroscope of the smallest dimensions.—On the phenomena of interference visible on mirrors covered with dust or a fine layer of grease, by Prof. M. Sekulic.—Researches on apparent adhesion, by J. Stefan.—On the conducting capacity of the halogen compounds of lead, by E. Wiedemann.

Transactions of the Manchester Geological Society, Part viii. vol. xiii., 1874-75.—Nearly the whole of this part is occupied by an elaborate illustrated paper on "Hæmatite Deposits," by Mr. J. D. Kendall. There is a short paper by Mr. A. W. Waters on "Tertiary Coals," in reference to specimens of carbonised peat he found in Northern Italy under rather peculiar circumstances. Part ix. is occupied with the discussion on Mr. Kendall's paper on Hæmatite deposits, and with a long paper on basalt and its effects, by Mr. G. C. Greenwell, F.G.S.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, April 29.—"On a Continuous Self-Registering Thermometer," by H. Harrison Cripps. Communicated by Prof. Stokes, Sec. R.S.

The instrument is divided into two portions :—First, the thermometer, which marks the degrees; secondly, the clockwork, which indicates the hours and minutes. The thermometer is first described. The form in which it was originally made, and which perhaps serves best for illustrating the principle, was the following :—A glass bulb, rather more than an inch in diameter, ends in a glass tube 12 inches long, having a bore of $\frac{1}{8}$ inch. This tube is coiled round the bulb in such a manner as to form a complete circle four inches in diameter, the bulb being in the centre of this circle. Fixed to opposite poles of the bulb, exactly at right angles to the encircling tube, are two needle-pointed pivots. These pivots work in minute metal depressions fixed to the sides of two parallel uprights. It will be seen from this arrangement that the bulb with its glass tube will rotate freely between the uprights, and the pivots will be the centre of a circle, the circumference of which is formed by the glass tube. The bulb is filled with spirit in such quantity that at 60° Fahrenheit the spirit will fill not only the bulb, but about 4 inches of the tube. Mercury is then passed into the tube till it comes into contact with the spirit, and in such quantity as to fill up about three inches of the remaining portion of the tube. The spirit is now heated to 120°, and as it expands forces the column of mercury in front of it till the mercury comes within $\frac{1}{4}$ inch of the end of the tube. The tube is then hermetically sealed, enclosing a small quantity of air. If the thermometer be now arranged with its needle-points between the uprights, it will be observed that, as the spirit contracts on cooling, it draws the column of mercury with it. This immediately alters the centre of gravity, and the bulb and tube begin to revolve in a direction opposite to that of the receding mercury. On again applying heat, and the mercury passing forwards, the bulb regains its original position. By this simple arrangement, the two forces, heat and gravity, acting in contrary directions, generate a beautifully steady rotatory movement. The method by which this movement is made serviceable for moving the register will now be described. A grooved wheel, two inches in diameter, is fixed to one of the central pivots, therefore revolving with the bulb. Directly above, and at a distance of seven inches from this wheel, is fixed between needle-points another wheel of exactly similar size. Around and between these two wheels passes a minute endless chain. To the chain is fixed a tiny pencil, which will be carried backwards and forwards between the wheels in a perpendicular line. This constitutes the register worked by the thermometer. The clockwork portion of the machine is so arranged that it causes a vertical cylinder, four inches diameter and five inches in length, to revolve once in twenty-four hours. Round this cylinder is fixed a piece of paper twelve inches long, five inches wide.

On the paper in the direction of its greatest length are ruled 100 lines, $\frac{1}{20}$ inch apart, each indicating 1° Fahrenheit. Across the paper, at right angles to these lines, are ruled twenty-four lines in dark ink, indicating the hours; between these three others, more lightly marked, for the quarters. The cylinder is so placed that as it revolves the surface of the paper is $\frac{1}{10}$ of an inch away from the point of the pencil register moving at right angles to its surface. A small striker is connected with the clockwork in such a manner that every five minutes (or oftener if required) it gives the pencil a gentle tap, thus striking its point against the paper. By this means all friction of the moving pencil against the paper is avoided, and the index is marked by a series of dots.

"Some particulars of the Transit of Venus across the Sun, 1874, Dec. 9, observed on the Himalaya Mountains, Mussoorie, at Mary Villa."—Note II., with appendix, by J. B. N. Hennessey, F.R.A.S.

Linnean Society, May 6.—Dr. G. J. Allman, F.R.S., president, in the chair.—The following papers were read:—On the anatomy of two parasitic forms of *Tetrarhynchidæ*, by Mr. F. H. Welch.—Notes on the Lepidoptera of the family *Zygænidæ*, with descriptions of new genera and species, by Mr. A. G. Butler, F.L.S. The main object of the paper was to rescue this section of Lepidoptera from the confusion into which it had been brought by the creation of new species and genera on insufficient grounds, by Mr. J. Walker. Some very curious instances of mimetism were mentioned between parallel series of species of hornet-moths and of Hymenoptera.—On the characteristic colouring matters of the red groups of Algæ, by Mr. H. C. Sorby, F.R.S. In this paper the author gave an account of some of the leading characters of the various remarkable blue, purple, and red substances soluble in water characteristic of red Algæ. The compound nature of the solutions obtained from the plants may be proved by the varying decomposing action of heat on the different colouring matters. He also showed that though *Oscillatoriæ* and *Rhodosporeæ* yield closely-related colouring substances, the specific differences serve to separate these two groups of Algæ quite as much as their general structure. Connecting links do indeed occur, and the further study of this question will probably yield interesting results. Specimens illustrating these facts were exhibited. A discussion followed, in which the President, Prof. Dyer, Mr. A. W. Bennett, and others took part.

Chemical Society, May 6.—Dr. Odling, F.R.S., vice-president, in the chair.—Prof. N. S. Maskelyne read a paper on Andrewsite and Chalcosiderite, the former of which is a new mineral from Cornwall named after Prof. Andrews. There were also papers entitled "An examination of methods for effecting the quantitative separation of iron, sesquioxide, alumina, and phosphoric acid," by Dr. W. Flight; and "On sodium ethylthiosulphate," by Mr. W. Ramsay.—Mr. J. Williams, in his communication "On a milligrade thermometric scale," proposes to substitute the freezing and boiling points of mercury for those of water, and to divide the scale into a thousand parts.—Mr. C. Griffin exhibited and described some new gas furnaces which are very economical and of great power.

Zoological Society, May 4.—Mr. E. W. H. Holdsworth in the chair.—Mr. Sclater exhibited and made remarks on a skin of a chick of a Cassowary (*Casuarius picticollis*), received from Dr. George Bennett, of Sydney, New South Wales. The bird had been obtained alive from the natives in Milne Bay, New Guinea, by Mr. Godfrey Goodman, Staff Surgeon, R.N., when in the *Basilisk* in 1873.—Prof. Newton exhibited and made remarks on a series of tracings of some hitherto unpublished drawings discovered in the Library of Utrecht, representing the Dodo and other extinct birds of Mauritius. Prof. Newton also exhibited and made remarks on two specimens of Ross's Arctic Gull, *Rhodostethia rossi*, one of the rarest of Arctic birds.—Mr. H. C. Sorby, F.R.S., read a paper on the colouring matter of the shells of birds-eggs as studied by the spectrum method, in which he showed that all their different tints are due to a variable mixture of seven well-marked colouring matters. Hitherto the greater part of these had not been found elsewhere. The principal red colouring-matter was connected with the hamoglobin of blood, and the two blue colouring matters were probably related to bile pigments; but in both cases it was only a chemical and physical relationship, and the individual substances were quite distinct, and it seemed as though they were special secretions. There appeared to be no simple connection between the production of these various egg-pigments and the general organisation of the birds, unless it were in the case of the Tinamous, in the shells of the eggs of many species of which occurs an orange-red substance not met with in any other eggs, unless it were in those of some species of Cassowary.—Mr. A. H. Garrod read a note on the hyoid bone of the Elephant, as observed in two specimens of the Indian Elephant which he had lately dissected, and showed that the position of the bone *in situ* had been mis-stated by former authorities.—A second paper by Mr. Garrod contained remarks on the relationship of two pigeons, *Ianthœnas leucolæma* and *Erythrœnas pulcherrima*, which he lately had an opportunity of examining.—A communication was read from Mr. G. E. Dobson on the bats belonging to the genus *Scotophilus*, in which he gave the description of a new genus and species allied thereto. The specimen in question had been obtained in the Bellary Hills, India, by the Hon. J. Dormer, by whom it had been presented to the British Museum. It was proposed to name it *Scotozous dormeri*.—A communication was read from Lieut. W. Vincent Legge, R.A., giving particulars of the breeding of certain Grallatores and Natatores on the south-eastern coast of Ceylon, together with notes on the nestling plumages of the same.

Geological Society, April 28.—Mr. John Evans, V.P.R.S., president, in the chair.—The following communications were read:—"On *Stagonolepis Robertsoni*, and on the evolution of the Crocodilia," by Prof. T. H. Huxley, Sec. R.S. After referring to his paper read before the Society in 1858, the author stated that he had since obtained, through the Rev. Dr. Gordon of Birnie, and Mr. Grant of Lossiemouth, further materials, which served at once to confirm the opinion then expressed by him, and to complete our knowledge of *Stagonolepis*. The remains hitherto procured consist of the dermal scutes, vertebræ of the cervical, thoracic, lumbar, sacral and caudal regions, ribs, part of the skull and the teeth, the scapula, coracoid and interclavicle, the humerus, and probably the radius, the ilium, ischium and pubis, the femur, and probably the tibia, and two metacarpal or metatarsal bones. The remains procured confirm the determinations given by the author in his former paper, except that the mandible with long curved teeth therein, superstitiously referred to *Stagonolepis*, proves not to belong to that animal. From the extant evidence it appears that in outward form *Stagonolepis* resembled one of the existing Caimans of intertropical America, except that it possessed a long narrow skull, like that of a Gavial. The dermal scutes formed a dorsal and ventral armour, but the dorsal shield did not contain more than two, nor the ventral shield more than eight longitudinal series of scutes. The posterior nares were situated far forward, as in lizards, neither the palatine nor the pterygoid bones uniting to prolong the nasal passage backwards, and give rise to secondary posterior nares, as in existing crocodiles. The teeth referred to *Stagonolepis* have short, swollen, obtusely pointed crowns, like the back teeth of some existing crocodiles; they sometimes present signs of wear. The scapula resembles that of recent crocodiles; the coracoid is short and rounded like that of the Ornithoscelida and of some lizards, such as *Hatteria*. The humerus is more Lacertian than in existing crocodiles. The acetabular end of the ischium resembles that of a lizard, and the rest of the bone is shorter dorso-ventrally and longer antero-posteriorly than in living crocodiles, thus resembling that of *Belodon*. The latter reptile, from the Upper Keuper of Würtemberg, is the nearest ally of *Stagonolepis*; both are members of the same natural group, and this must be referred to the order Crocodilia, which was described as differing from other Reptilia as follows:—The transverse processes of most cervical and thoracic vertebræ are divided into more or less distinct capitular and tubercular portions, and the proximal ends of the corresponding ribs are correspondingly divided; the dorsal ends of the subvertebral caudal bones are not united; the quadrate bone is fixed to the side of the skull; the pterygoids send forward median processes which separate the palatines and reach the vomer; there is an interclavicle, but no clavicles; the ventral edge of the acetabular portion of the ilium is entire or but slightly excavated; the ischia are not much prolonged backwards, and the pubes are directed forwards and inwards; the femur has no inner trochanter, and the astragalus is not a depressed concavo-convex bone with an ascending process. There are at least two longitudinal rows of dorsal dermal scutes. The Crocodilia are divided by the author into three sub-orders:—

1. Parasuchia, with no bony plates of the pterygoid or palatine bones to prolong the nasal passages; the Eustachian pas-

sages enclosed by bone; the centra of the vertebræ amphicœlian; the coracoid short and rounded; the ala of the ilium high, and its acetabular margin entire; and the ischium short dorso-ventrally and elongated longitudinally, with its acetabular portion resembling that of a lizard. Genera: *Stagonolepis*, *Belodon*.

2. Mesosuchia, with bony plates of the palatine bones prolonging the nasal passages, and giving rise to secondary posterior nares; a middle Eustachian canal included between the basioccipital and basisphenoid, and the lateral canals represented only by grooves; vertebral centra amphicœlian; coracoid elongated; ala of the ilium lower than in the preceding, higher than in the next sub-order, its acetabular margin nearly straight; ischium more elongated dorso-ventrally than in the preceding group, with its acetabular margin deeply notched. Genera: *Steneosaurus*, *Pelagosaurus*, *Teleosaurus*, *Teleidosaurus*, *Metriorhyncus* (*Goniopholis*?, *Pholidosaurus*?).

3. Eusuchia, with both pterygoid and palatine bones giving off plates which prolong the nasal passages; vertebral centra mostly procœlous; coracoid elongated; ala of the ilium very low in front, its acetabular margin deeply notched; ischium elongated dorso-ventrally, with its articular margin deeply excavated. Genera: *Thoracosaurus*, *Holops*, and recent forms.

The Mesosuchia are intermediate in character between the other two groups; the Parasuchia, where they differ from the Mesosuchia, approach the Ornithoscelida and Lacertilia, especially such as *Hatteria* and *Hyperodapedon*, with amphicœlous vertebral centra. The Eusuchia, on the other hand, are the Crocodilia which depart most widely from the Ornithoscelida and Lacertilia, and are the most Crocodilian of crocodiles. After indicating at some length the succession of modifications in the above three groups, the author remarked that if there is any solid ground for the doctrine of evolution, the Eusuchia ought to be developed from the Mesosuchia, and these from the Parasuchia, and showed that geological evidence proved that the three groups made their appearance in order of time, in accordance with this view. Thus, in the Trias there are the genera *Belodon* and *Stagonolepis* of the sub-order Parasuchia. In the Upper Lias we have *Steneosaurus* (*Mystriosaurus*) and *Pelagosaurus*, the first represented also in all Mesozoic formations up to the Kimmeridge Clay; in the Fuller's Earth *Teleosaurus* and *Teleidosaurus* occur; in the Kelloway Rock *Metriorhynchus*, also met with in the Oxford Clay and Kimmeridge Clay; in the Wealden, *Goniopholis*, *Macrorhynchus*, *Pholidosaurus*, and unnamed Teleosaurians; and in the Upper Chalk, *Hyposaurus*; all belonging to the Mesosuchia. In the Upper Chalk, again, the Eusuchia make their appearance, represented by the genera *Thoracosaurus*, *Holops*, and *Gavialis* (?). How far back the Parasuchia extend in time is not known, but they are not found in any formation subsequent to the Upper Trias. The author described a fragment of a skull of a Wealden crocodile, in which the posterior nares are smaller and situated further back than in *Metriorhynchus* or *Steneosaurus*. Of the nearest allies of the Crocodilia, the Lacertilia and Ornithoscelida, the former may be traced back from the present day to the Permian epoch, and the latter from the later Cretaceous to the Triassic epoch. The author discussed the question whether these types exhibit any evidence of a similar form of evolution to that of the Crocodilia. The cranial structure of the Permian Lacertilia is almost unknown, and the only important deviation from the type of the existing Lacertilia in the skeleton is that their vertebræ are amphicœlous, not procœlous. With this exception there is no evidence that the Lacertilian type of structure has undergone any important change from later Palæozoic times to the present day; and this change seems to have occurred earlier in the Lacertilia than in the crocodiles, as a sacral vertebra of a lizard from the Purbecks has the centrum concave in front and convex behind. With regard to the Ornithoscelida, the author noticed that the researches of American palæontologists proved the existence of those reptiles in abundance in quite the latter part of the Cretaceous epoch. He had himself indicated the existence of varied forms of Dinosauria in the Trias. He confirmed his former opinion that *Zanclodon* from the Upper Keuper of Würtemberg is a Dinosaur, and probably identical with *Teratosaurus* (von Meyer), in which case its affinity to *Megalosaurus* is exceedingly close. He corrected a statement in a former paper with regard to the ilium of the Thecodontosaurians, which he had turned the wrong way, and stated that when regarded in its proper position this ilium is much more Lacertilian than that of *Megalosaurus*. From this and other evidence of detail he inferred that the Triassic Thecodontosauria were devoid of some of the most marked peculiarities of the later Ornithoscelida, while the most ornithic of the latter belong to the second half of the Mesozoic period. The oldest crocodiles differ less than the recent ones from the Lacertilia, and the oldest Ornithoscelida also approach a less differentiated Lacertilian form, the two groups seeming to converge towards the common form of a lizard with Crocodilian vertebræ. *Cetiosaurus* is also a reptile with a vertebral system like that of the Thecodontosauria and Crocodilia, but with more Lacertilian limbs, and *Stenopelyx* may be in the same case. It may therefore be convenient hereafter to separate the Thecodontosauria, *Cetiosaurus* and perhaps *Stenopelyx* as a group, "Suchospondylia," distinct from both the Ornithoscelida and the Crocodilia (or "Sauroscelida").

"On the remains of a fossil forest in the Coal-measures at Wadsley, near Sheffield," by H. C. Sorby, F.R.S., Pres. R.M.S. In this paper the author described the occurrence of a number of stumps of *Sigillariæ* in position and with Stigmarian roots attached to them in the Coal-measure Sandstone in the grounds of the South Yorkshire Lunatic Asylum.—"On *Favistella stellata* and *Favistella calicina*, with notes on the affinities of *Favistella* and allied genera," by Mr. H. Alleyne Nicholson, F.R.S.E.

Mr. A. Tylor brought an apparatus for determining the heat evolved by the friction of ice upon ice, with a view to explain an important element in glacier motion. The apparatus, consisting of plates of ice eight inches square, placed in a wooden chuck three inches deep, was enclosed in a double sheet-iron case containing ice and salt, and kept at 32° F. One block of ice was rotated, and the other pressed against it. Four pounds of ice were reduced to water at the rate of $1\frac{1}{4}$ lb. in an hour, in consequence of the motion, that is by the heat evolved by friction of ice upon ice, the pressure being 2 lbs. on the square inch. Ice evaporates at 32°, and the same quantity of ice was reduced, when still, at about the rate of $\frac{1}{4}$ lb. in an hour at 32° F. Air at a higher temperature found its way into the case, and promoted melting. When this experiment was tried in a room at 54° F. with the same apparatus without any outer case, the friction of the ice in motion, at the above pressure, increased the production of water $3\frac{1}{4}$ times above the rate observed when the ice was still and exposed to a temperature of 54° F. The amount of heat evolved was nearly as much as in oak moving upon oak well lubricated, and the coefficient of friction was between 0·1 and 0·2. Glacier motion is impossible without a continual supply of water to lubricate the bottom. No doubt the action of denudation by glaciers produces heat to a small extent. The water obtained by melting the surface of the glacier by the sun's heat in the glacial period could not be sufficient alone. The position of deep lakes in all parts of the world in immediate connection with mountains, and never in places away from mountains, shows that lakes are integral parts of mountains; and, in fact, lakes are deepest exactly where the glaciers, once covering the mountains, were in a position to act as lake excavators. There can be no doubt that all deep lakes in the world, including those in Central Africa, below the Equator, are purely of glacial origin, and that the cold in the glacial period was nearly equally intense in the southern and northern hemispheres. The surface-ice would move much faster than the bottom ice, and the side-ice than the surface-ice, and therefore fractures would be continually occurring through all parts. The water produced by this great friction of ice upon ice would fall through the fissures to the bottom. He had pointed out that a glacier moved twice as fast when it was eight times as thick, and the influence of weight on motion must be considered a most important element. The present temperature of a thin glacier was found by Agassiz, from observation, to be one-third of a degree below freezing; but Mr. Tylor assumed that in such a lake-glacier as he had drawn, and supposed to exist in the glacial period, the temperature might be assumed to be very much below freezing, the greater cold arising from immense evaporation and other causes. He therefore concluded that the water produced by friction of ice upon ice falling to the bottom of the lake glacier through fissures would rapidly freeze, and thus expanding one tenth, would impel the glacier (shod or armed with blocks of stone and sand at the bottom) up a gradient of 1 in 20, excavating the Swiss and other lakes thirty or forty miles long, and 1,200 feet deep, in this manner. Mr. Tylor calculated that with half the work per annum of mean lake-excavation the lake of Zurich could be excavated in 15,000 years. Prof. Ramsay had pointed out, from geological evidence, that such lakes have been excavated by ice, but he did not indicate how this was mechanically possible (see *Quarterly Journal*, 1862). Mr. Tylor referred again to his experiment when the pressure was only 2 lbs. on the inch. In a large glacier

such as that described by Dr. Hooker in the Himalayan range, where the mean gradient of the surface was 40° to 50° and the actual fall was 14,000 feet in five or six miles, Dr. Hooker found great lakes attendant upon the mountains. Supposing the ice was a mile thick, the pressure would be half a ton on the inch, in the Himalayas at least, and the production of water by friction of ice upon ice enormous. Friction is dependent upon pressure and distance moved, and independent of velocity of motion.

Anthropological Institute, April 27.—Col. A. Lane-Fox, president, in the chair.—Mr. Francis Galton, F.R.S., contributed a note on the height and weight of boys aged fourteen, in town and country schools. The principal results showed the comparative heights and weights of those boys who were fourteen on their last birthday, in two groups of public schools, the one group of country schools and the other of town schools. It appeared that boys of fourteen in the country group were about $1\frac{1}{4}$ inches taller and 7 lbs. heavier than those in the town group, and that the difference of height was due in about equal degrees to retardation and to total suppression of growth; and that the distribution of heights in both cases conformed well to the results of the "Law of Error."—Rev. Joseph Mullens, D.D., read a paper on the origin and progress of the people of Madagascar. The Malagasy appeared to be a single race. No tribe is to be found secluded in any corner or in the hill districts different from the people of the plains or open provinces such as is met with in India, in Sumatra, and in Borneo; nor is any portion of the people specially degraded. The Malagasy are divided into three tribes—the Betsimisarakas, the Sacalavas, and the Hovas, the latter largely predominating in numbers and influence. With regard to the origin of the people, the author rejected the theory of Crawfurd and others, who argued for their African descent. Their language and tribal customs suggested a very different origin. There could hardly be any doubt that the Malay entered largely into the composition of the grammar and vocabulary, and continued researches into the Malay and Malagasy languages gave more and more evidence of their resemblances. The conclusion was that the Malagasy are a Malay people, following Malay customs, some of them possessing Malay eyes, hair, and features, and speaking a Malay tongue at the present time. They were an intelligent people, orderly, were well governed, and were daily improving, and the author of the paper could see the promise of a great and useful future for them.—Mr. J. J. Monteiro read a paper on the Quissama tribe of Angola, which he had written with the object of correcting some erroneous statements concerning them that had been formerly brought before the Institute.

CAMBRIDGE

Philosophical Society, March 8.—The following communications were made by Mr. W. T. Kingsley:—(1) On the cause of the "wolf" in the violoncello; (2) A description of the instruments used in sounding some of the lakes in the Snowdon district, and an account of the results obtained. Mr. Kingsley said that the "wolf" occurs somewhere about the low E or E flat, and was attributed to the finger-board having the same pitch, so that the finger-board becomes as it were a portion of the string stopped down on it and vibrates with it: if this is the true cause, the "wolf" cannot be got rid of, but may be placed at such a pitch between E and E flat as to occur on a note rarely used; also by thickening the neck of the finger-board, the extent of discursion in the vibration may be made less.—The Master of St. Catharine's College remarked that a different explanation of the phenomenon was given by M. Savart, which was to this effect. The old Italian makers constructed the violoncello of such dimensions that the mass of air included within the instrument resonates to a note making 85·33 vibrations in a second, a number which then represented the lowest F on the C string, but which now, owing to the rise of pitch since the beginning of the eighteenth century, nearly represents the note E immediately below it. Savart's theory was that notes half a tone above or below this E will cause beats between the vibrations of the string and those of the mass of included air. It seemed quite possible that the mass of air contained in the instrument should be capable of controlling the vibrations of the whole instrument, but not that the vibrations of the finger-board alone (as Mr. Kingsley suggested) could do this. For the sound, technically called the "wolf," is an actual check to the whole vibration of the violoncello, producing not merely beats, but a baying sound, destitute of the freedom of vibration which characterises other notes. But a great objection to the above explanation is this experiment. On an Italian instrument, the upper D on the fourth or lowest string is the imperfect note. But when the same note is elicited from the third string, the note is perfectly resonant. This peculiar effect seems then to depend upon the point of the finger-board which is pressed. It is also well known that the "wolf" can be modified by an alteration of the position of the sound-post. As an explanation, we may conceive that the whole framework of the violoncello vibrates like a stretched string, producing its fundamental, with a series of overtones, and that a nodal line passes through the point of the finger-board, pressure upon which produces the "wolf," and that thus, all vibrations being destroyed except those which have a node at the point of pressure, this peculiar tone is elicited.—Mr. Kingsley then gave a description of the plummet, registering apparatus, and protractors used by him in sounding several of the deep lakes in the Snowdon district last June. The plummet is a modification of the deep-sea plummet now generally used, the principal alteration being in the application of a heavy gouge to aid in bringing up specimens of the bottom. The recording apparatus is a modification of the paying-out apparatus used for laying deep-sea telegraph cables. The protractors are diagonal telescopes mounted on bars revolving on vertical axes, and having fiducial edges radiating from the centres of the axes. One protractor is placed at each extremity of the base on a horizontal table, on which is strained a sheet of drawing paper; the telescopes are first collimated with each other, and then a line is drawn by the fiducial edges on each sheet of paper; the boat with the sounding apparatus is followed by the two observers at the protractors, and when a signal is given, a line is ruled and numbered by each observer; finally, the two papers are placed so as to have the lines of collimation in coincidence and the centres at the scale distances apart; then by looking through the papers and pricking the intersections of the corresponding lines, the positions of the boat are laid down on two maps. In practice this is all done easily, and no particular skill is needed in the observers with the protractors. The results obtained showed that the bottoms of these lakes are comparatively flat, the greatest depths being reached at a short distance from the shore on the cross section, and occurring also nearer to the upper end of the lake than to the lower: the forms of the bottoms correspond in a remarkable manner with the set that would be given to glaciers descending into the hollows in which the lakes lie; and Mr. Kingsley believed them to have been formed by the action of glaciers during the extreme cold or penultimate glacier epoch; because in one case, that of Llyn Cawlyd, the lake lies almost on a watershed, where no glacier could now form, but which was a depression forming a lateral outflow from the great glacier that at one time filled the whole hollow between the Glydyns and Carnedds; during the last glacier epoch most of these hollows were again filled with ice to a great height, but these last glaciers were comparatively small. Mr. Kingsley especially dwelt upon the difficulty of disentangling the scattered moraine from the drift, and also of distinguishing between the striations belonging to the two cold epochs.

THE UNSEEN UNIVERSE

The Unseen Universe; or, Physical Speculations on a Future State. (London: Macmillan and Co., 1875.)

THIS book, which rumour attributes to a co-partnery of two distinguished physicists, will at least serve to prove one thing, that scientific men are not necessarily unbelievers, and that some scientific men accept frankly and fully the whole of what is generally understood as the scheme of Trinitarian Christianity, and find in it the most adequate expression of their own physical speculations. Whether their readers agree with or differ from the authors, they cannot fail to recognise the extent of their information and the freedom of their reasoning. There is no attempt to make anything square with preconceived theories, and although we doubt whether the writers would have arrived at their conclusions without the accepted scheme of orthodox Christianity to serve them as a clue, it is equally clear that they rest them on what they think adequate scientific evidence.

The preliminary chapter states the fact of the all but universal belief in, or aspiration after, Immortality. It admits that that doctrine is inconsistent with the doctrine of continuity as generally understood and as applied solely to the visible universe. It accepts and explains the principle of continuity in the fullest sense, and it attempts to reconcile it, as thus apprehended, with the doctrine of immortality. Incidentally—out of the apparent waste of energy in space, and on other indications chiefly teleological—it constructs a hypothesis of an invisible universe, perhaps developed out of another invisible universe, and so on *ad infinitum.* It is another consequence of the theory that our natural bodies are probably accompanied by a sort of invisible framework or spiritual body, and that the phosphorus and other substances of which the natural body is built up are not really identical with these elements in their ordinary condition of inorganic atoms, but are somehow transubstantiated by the co-existence, along with the mere chemical substance or with its chemical properties, of this invisible, imponderable, immaterial, accompanying essence, which derives a kind of *vis vivida* from a connection with the unseen universe. The passage from the visible universe to the invisible seems to be made intelligible to the authors by the existence of the ether, a substance into which energy is continually being passed, and into which it is perpetually, and, so far as any obvious or sensible effect is concerned, finally, absorbed.

As a first postulate the authors assume the existence of a Creator. Finite beings, creatures, are conditioned by the laws of the universe, and it is in these conditions that we must seek to discover its nature. The first pair of subjects for human thought are matter and mind, and the materialists tell us, that whereas mind or mental activity never exists without being associated with some forms of matter, we may perfectly conceive matter, as for instance a block of wood or a bar of iron, existing without intelligence. Is mind then the dependant—is there nothing in matter which serves as the vehicle of intelligence different from all other matter? The authors answer that we have no right to assume that the brain consists of particles of phosphorus or carbon such as we know these substances chemically, that we cannot say that there may not be something superadded to their chemical and physical qualities. They dwell upon another fact—the fact that individual consciousness returns after sleep or trance; a fact inferring some continuous existence. The assumptions of the materialist are less inevitable than he supposes. Turning to mind, finite conditioned intelligence, the authors ask, what is essential to it? It must have some organ by which it can have a hold upon the past, and such a frame and such a universe as supply the means of activity in the present. Outside they find physical laws, and they look on the principle of continuity as something like a physical axiom. By this principle we are compelled to believe that the Supreme Governor of the Universe will not put us to permanent intellectual confusion. It is in the nature of man, certainly in the nature of scientific man, to carry the explanation of everything back *ad infinitum*, and to refuse perpetually to grant what is perpetually demanded of him, that he has arrived at the inexplicable and unconditioned. On this principle scientific men have supposed themselves to prove that the physical universe must one day become mere dead matter. The authors consider that this is a monstrous supposition, although they grant that the *visible*, or by-sense-perceivable universe, *must in transformable energy, and probably in matter*, come to an end. They think that the principle of continuity itself demands a continuance of the universe, and they are driven to believe in something beyond that which is visible as the only means of explaining how this system of things can endure in the future, or can have endured for ever in the past. They see a visible universe, finite in extent and finite in duration, beyond which, o both sides stretching infinitely forward and infinitely backward, there is an invisible, its forerunner and its continuation. It is natural to infer that these two invisibles must meet across the existing finite visible universe. As we are driven to admit the invisible in the past and in the future, there must be an invisible framework of things accompanying us in the present.

What then is this present visible universe; and can we point to sure signs of this invisible substance which accompanies what may prove after all to be the mere shadow of things? Matter has two qualities. The first is that it is indestructible; the second, that the senses of all men alike point to the same quantity, quality, and collocation of it. Our practical working certainty of the existence of matter means (1) that it offers resistance to our imagination and our will; and (2) that it offers absolute resistance to all attempts to change its quantity. Certain other things—notably energy—are in the same sense conserved, and if we recognise the transmutability of energy of motion into energy of position, we may say that energy is equally indestructible with matter itself. But energy is undergoing a perpetual self-degradation. All other forms of energy are slowly passing into invisible heat motions, and when the heat of the universe has ultimately been equalised, as it must be, all possibility of physical action or of work will have departed. Mechanical effort cannot longer be obtained from it. The perfect heat-engine only converts a portion of the heat into work; the rest is lost for ever as an available source of

work. There is indeed a sort of wild and far-off possibility by which a little more work *might* be got out of a uniform temperature universe, if we could suppose Clerk-Maxwell's demons—"mere guidance applied by human intelligence"—occupied in separating those particles of a heated gas which are moving faster than the average from those which are moving slower. But this is but a broken reed to trust, and it would at the best avail us little. What must happen in the existing physical system would be this: the earth, the planets, the sun, the stars, are gradually cooling; but infinitely numerous catastrophes by which the enormous existing store of energy of position may be drawn upon, may over and over again restore unequal temperature. The fall together, from the distance of Sirius, of the sun and another equal sun would supply the former with at least thirty times as much energy as can have been obtained by the condensation of his materials out of a practically infinite nebulous mass of stones or dust. But these catastrophes can only delay the inevitable. If the existing physical universe be finite—and the authors never seem to realise the speculative possibility that it may not be so—the end must come, unless there be an invisible universe to supplement and continue it.

What is the ultimate nature of matter, and especially of the ether, which is the vehicle of all the energy we receive from the sun? There have been four theories, for each of which something may be said. There is the Lucretian theory of an original, indivisible, infinitely hard atom, "strong in solid singleness;" Boscovich's theory that the atom or unit is a mere centre of force; the theory that matter, instead of being atomic, is infinitely divisible, practically continuous, intensely heterogeneous; and, finally, the theory of the vortex atom, a thing not infinitely hard and therefore indivisible, but infinitely mobile, so that it escapes all force which makes effort to divide it. What we call matter may thus consist of the rotating portions of a perfect fluid, which continuously fills space. Should this fluid exist, there must be a creative act for the destruction or production of the smallest portion of matter. Whichever of these theories we adopt, we must explain the simplest affection of matter—that by which it attracts other matter. There seems little possibility of doing so. The most plausible explanation is in Le Sage's assumption of *ultramundane corpuscles*, infinite in number, excessively small in size, flying about with enormous velocities in all directions. These particles must move with perfect freedom among the particles of ordinary matter, and if they do so we can understand how, through the existence of the ultramundane particles, two mundane particles attract inversely as the square of the distance. On this theory the energy of position is only the energy of motion of ultramundane and invisible particles—and a bridge is built between the seen and the unseen. These ultramundane particles are something far more completely removed from all possibility of sensible qualities than the ether which Sir William Thomson has attempted to weigh. Struve has speculated upon the possibility that it is not infinitely transparent to light, and his calculations, based on the numbers of stars of each visible magnitude, lead him to suppose that some portion of the light and energy from distant suns and planets may be absorbed in it. The ether is thus a kind of adumbration or foretaste of the invisible world. It may have certain of the properties of that world which is perceived by sense, but it is probably subject only to a few of the physical conditions of ordinary matter.

Let us look once more at the substance of the universe. We recognise that it is impossible to suppose any existing state but as the development of something pre-existing. To suppose creation, is to suppose the unconditioned. Creation belongs to eternity, and not to time. This being so, it is difficult to believe in the vortex ring theory, which regards the invisible universe as an absolutely perfect fluid. With an imperfect fluid, the eternity of visible matter which the vortex theory requires, disappears. Such a visible universe would be as essentially ephemeral as a smoke-ring—so that we may accept it as possible, if not probable, that the visible universe may pass away—that it may bury its dead out of its sight. In its present state we have three forms of development—Chemical, or Stuff Development, Globe Development, and Life Development. It is a question whether the ultimate atoms of chemists are really ultimate; whether some agent, like great heat, for instance, could not split them up into various groups of some primal substance like hydrogen. We see the prospect of a similar simplicity in the development of worlds on the theory of Kant and Laplace, which makes the systems of the universe the result of the gradual condensation of nebulous masses. In the end, all the masses of the universe must fall together—in the beginning there can have been no masses, everything being nebulous and discrete, even if ordinary matter be indestructible. The last state and the first state of the visible universe are thus separated from each other by a finite duration. A like simplicity may be reached in the development of life. Darwin has made it at least possible that all life may issue from some primordial life-germ. The complete refutation of the doctrine of abiogenesis—the practical proof that life issues only from life—leaves us still bound to account for that germ. There is no doubt that species develop varieties which may ultimately become distinct species, although there is little indication that the varieties of what was once one species are ever separated like species originally different, by a barrier of mutual infertility. A sufficient length of time might enable us to overcome this barrier. In all our developments—the substance development, the globe development, the life development—we are thus brought, in the end, to a something which we are not yet able to comprehend.

Turning from matter to the phenomena which affect it, we notice one singular set of phenomena in which things insignificant and obscure give rise to great lines of events. A whole mass of water, the temperature of which has been reduced below the freezing-point, suddenly crystallises on the slightest starting motion; a whole series of tremendous meteorological phenomena, such as hurricanes in the Indian Ocean, happen because certain positions of Mercury and Venus affect the sun's atmosphere, causing spots in his, and the condition of the sun affects the earth. Like the complicated series of effects which follow the pulling of the trigger of a gun, the effects are utterly disproportionate to their causes. Man is a machine of this unstable kind—some trivial

change affecting the matter of the brain is all that i needed to set him in motion. May not other beings be capable of touching what we may call the hair-triggers of the universe? Whatever these agencies are, angels or ministering spirits, they certainly do not belong to the present visible universe. The writers examine the sacred records to confirm their speculations.

Thus, then, we have a visible and an invisible universe, and we have processes of delicacy in the former which at least suggest the action on it of agencies belonging to the latter. Let us look at the first phenomenon of the visible universe—the expenditure of energy in it. The sun's energy is issuing in what is apparently waste space just as it is issuing in that portion of space which is filled by our earth. What becomes of the energy—probably far more than half of that which proceeds from it—which proceeds apparently nowhere, speeding on with the velocity of light? Is it absorbed in the ether, and if so, what does the ether do with it? The writers suggest that the ether may preserve for intelligent beings the record of the past. But that seems scarcely sufficient use of the energies spent on it; the more so as the intelligent beings existing in the visible universe will certainly come to an end with it.

"We were led," say the authors, in a passage in which their whole theory is perhaps summed up, "to conclude that the visible system is not the whole universe, but only, it may be, a very small part of it; and that there must be an invisible order of things, which will remain and possess energy when the present system has passed away. Furthermore, we have seen that an argument derived from the beginning rather than the end of things assures us that the invisible universe existed before the visible one. From this we conclude that the invisible universe exists now, and this conclusion will be strengthened when we come to discuss the nature of the invisible universe, and to see that it cannot possibly have been changed into the present, but must exist independently now. It is, moreover, very closely connected with the present system, inasmuch as this may be looked upon as having come into being through its means.

"Thus we are led to believe that there exists now an invisible order of things intimately connected with the present, and capable of acting energetically upon it—for, in truth, the energy of the present system is to be looked upon as originally derived from the invisible universe.

"Now, is it not natural to imagine that a universe of this nature, which we have reason to think exists, and is connected by bonds of energy with the visible universe, is also capable of receiving energy from it? Whether is it more likely that by far the larger portion of the high-class energy of the present universe is travelling outwards into space with an immense velocity, or that it is gradually transferred into an invisible order of things? May we not regard ether or the medium as not merely a bridge between one portion of the visible universe and another, but also as a bridge between one order of things and another, forming as it were a species of cement, in virtue of which the various orders of the universe are welded together and made into one? In fine, what we generally call ether may be not a mere medium, but a medium *plus* the invisible order of things, so that when the motions of the visible universe are transferred into ether, part of them are conveyed as by a bridge into the invisible universe, and are there made use of or stored up. Nay, is it even necessary to retain the conception of a bridge? May we not at once say that when energy is carried from matter into ether it is carried from the visible into the invisible; and that when it is carried from ether to matter it is carried from the invisible into the visible

"If we now turn to thought, we find that, inasmuch as it affects the substance of the present visible universe, it produces a material organ of memory. But the motions which accompany thought will also affect the invisible order of things, and thus it follows, that '*Thought conceived to affect the matter of another universe simultaneously with this may explain a future state*' (see Anagram, NATURE, Oct. 15, 1874)."

Our notice has already extended so far that we shall not follow the authors into their examination of the Scriptures, and of certain Christian hymns in which the sentiments and feelings of the Christian world seem to them to be embalmed. We notice only two of the objections to their system, which they themselves state, and seem to us to fail to refute. It is said that "if energy is transferred from the visible into the invisible universe, its constancy in the present universe can no longer be maintained." The answer is, that this visible universe is not the whole universe, and that the conservation of energy principle is applicable only to the whole universe, visible and invisible together, except under special limitations. The retort is obvious, that in this sense, and except when these special limitations specially and finally remove the difficulty, the principle becomes unintelligible and useless. It is a mere theological dogma to say that what energy perishes in the visible passes into the invisible universe; and the dogma is worthless as a physical principle on which to build any physical reasoning. The other objection is, that the dissipation of energy must go on even in this invisible universe, and the new assumption only delays the inevitable end of all things. The answer made is, that the universe may be regarded as an infinite whole. We have no objection, but the same may be said of the visible universe, and the moment that it is so regarded the arguments on which its end and its beginning are inferred seem to vanish into air. An infinite universe will have an infinite store of energy, and there is no need to suppose that its store is ever exhausted, or that in any finite time it has become practically degraded and unavailable. The whole elaborate machinery of the invisible universe (p. 171), piled one on the top of the other, seems to us to fall like a house of cards, if we can accept the eternal duration of an infinite by-sense-perceptible universe.

The book is written in a simple and persuasive style, with a transparent simplicity and purity of purpose. Once or twice there is an outburst of irrepressible energy, like that on pp. 106 and 107, about wife-beaters, who are to be subjected "by an enlightened Legislature to absolutely indescribable torture, unaccompanied by wound or even bruise, thrilling through every fibre of the frame of such miscreants." But these outbursts are transient, and they relieve the strain on the reader's attention.

THE TIDES OF THE MEDITERRANEAN

Az Arapály Fiumei Obölben (*The Tides in the Roadstead of Fiume*). Prize Essay, published by the Royal Philosophical Society of Hungary. By E. Stahlberger, Professor in the Imperial Royal Marine Academy. (Buda-Pesth, 1874, 4to., pp. 109, with plates and copious tables.)

FEW points in physical geography have had more interest for scientific men than the tides of the Mediterranean. Connected with the Atlantic only by a

strait of a few miles in width, this inland sheet of water is so effectually shut off from the general tidal movements of the main ocean, that it has often been called a "tideless sea." But this is not correct; for, having an extent of surface of some 700,000 or 800,000 square miles, it is sufficiently large to be itself specially affected by the attraction of the sun and moon, and thus it possesses a true, although small, tide of its own.

The daily variations in the level of the water have of course been always patent to the dwellers on the Mediterranean coasts; and, no doubt, careful observers must have remarked a periodicity in the recurrence of such variations, identifying them to a certain extent with the ocean tides. But from the small amount of the true periodical rise and fall, and from the large influence of accidental causes, the phenomena have been so irregular as to present great difficulties in their analysis; and, so far as we know, there has not been, down to the appearance of the present work, any systematic investigation of the subject put on record.

The present publication has arisen from a prize of 200*l.* having been offered in 1872 by the Royal Hungarian Society (from funds furnished by Government) for scientific labours bearing on the physical or meteorological conditions of the kingdom of Hungary.

Fiume is a town of some importance, lying on what is called the Hungarian *littorale*, washed by the waters of the Gulf of Quarnero, an irrregular-shaped recess in the extreme north-eastern part of the Adriatic. The Government of Hungary, desirous to promote the maritime interests attached to their little seaport, have established there a Marine Academy, and M. Stahlberger, one of the professors in that institution, had had occasion to make and register observations on the rise and fall of the water in the neighbouring roadstead. Conceiving that by studious labour the phenomena he had recorded might be reduced to something like rule and order, he undertook the elaborate theoretical discussion of them, and the Society, appreciating the value of the work, has not only awarded him the prize for it, but has published it, in full detail, for the benefit of science in general.

The author was led to this investigation by the double object of obtaining accurate information, first, as to the general phenomena of the tides in the Adriatic, or rather in the Mediterranean generally; and secondly, as to the peculiarities in these phenomena induced by local influences in the neighbourhood of the port of Fiume.

He remarks, in regard to the first point, that the semi-mensual irregularity which it is customary to deduce from observations, in order to predict the times of high and low water, is altogether different in the Adriatic from what obtains in regard to the ocean generally; and yet the causes of this difference have never yet been explained.

In regard to the second point, he refers to notices that had appeared of remarkable irregularities in the Fiume tides, which rendered further investigation very desirable. It had been perceived, that instead of the usual six hours' alternating ebb and flow, there was frequently only one high and one low water in the day; and, moreover, that the time of the lowest water advanced on the average two hours every month, or twenty-four hours in a year.

These strange phenomena had attracted attention, and in 1868 the Adria Commission of the Imperial Academy of Sciences at Vienna established a self-registering tide-gauge at Fiume, the control of which was entrusted to M. Stahlberger. The present essay contains the results of three years' observations, which are fully and scientifically discussed by him.

The tide-gauge was on a plan that has often been used in this country. It consisted of a float, which by means of connecting machinery and a pencil made a mark on a sheet of paper stretched on a drum. The drum being moved uniformly by clockwork so as to make one revolution in twenty-four hours, the height of the tide at any time of the day could be deduced by simple measurement from the curve produced on the paper. The same paper was used for three days' observations, the curves being distinguished from each other by different coloured pencils being attached at the beginning of each day.

The author appears to have gone to work in his investigation in a thoroughly philosophical way. He has first collected a very large number of facts, as shown by the records of his gauge; he has then tabulated them with great care and ingenuity, classifying them with special reference to the nature of the influences known to be in operation, such as the positions of the heavenly bodies, the direction and force of the wind, the state of the barometer, and so on; and finally, working on the records thus arranged, he has, by applying scientific calculations of a high order, been able to a large extent to simplify the complicated questions involved, and to throw much light on their explanation.

To facilitate the investigation, he divides the tidal phenomena into two classes: namely, in the first place, periodical motions of the water produced by cosmical causes; and secondly, non-periodical motions produced by the influence of meteorological or local agencies. He then discusses each of these two divisions at considerable length.

As to the periodical motions, he found that in calm weather, and even to a less extent at unsettled times, the figures drawn by the gauge showed unmistakable signs of periodicity; but the appearances were of two kinds: sometimes they showed two well-defined maxima and minima, six hours apart; at other times there was only a single maximum and minimum, sharply defined, these two types melting into each other with all gradations.

These regular forms were clearly to be referred to the periodical motions of the heavenly bodies, and the author, having carefully collected and arranged the facts, enters into a long and full theoretical discussion of their causes, according to the principles laid down by Newton and Laplace.

We cannot pretend to give any details of the laborious mathematical calculations which follow: it must suffice to extract the author's brief summary of his results on this head. He says that the periodical movements of the sea in the Gulf of Fiume depend in the first place on four simple oscillations, two of the sun and two of the moon; and secondly, on four other simple vibrations, two due to each body, which are reckoned in sidereal time, but which have only a slight effect, and may be neglected in computation.

If δ_m and δ_s represent the declinations of the moon and sun respectively, ρ_m and ρ their distances (expressed in terms of their respective mean distances), t_m and t_s the numb

of lunar or solar hours (Mondbeziehungsweise Sonnenstunden) which have elapsed since the last upper culmination of either body respectively; then the theoretical elevation or depression of the sea in the Gulf of Fiume due to these causes for any given time is found in millimetres by the expression :—

$$112{\cdot}1 \; \frac{\cos^2\delta_m}{\rho_m^3} \cos\frac{\pi}{6}\,(t_m - 8{\cdot}49)$$
$$+ \; 272{\cdot}4 \; \frac{\sin 2\delta_m}{\rho_m^3} \cos\frac{\pi}{12}(t_m - 4{\cdot}60) + 60{\cdot}3 \; \frac{\cos^2\delta_s}{\rho_s^3} \cos\frac{\pi}{6}\,(t_s - 8{\cdot}57)$$
$$+ \; 130{\cdot}4 \; \frac{\sin 2\delta_s}{\rho_s} \cos\frac{\pi}{12}\,(t_s - 4{\cdot}46)$$

This is the theoretical amount, not allowing for any local retardation, or any influence of the weather.

The author has calculated this for a great variety of conditions of the variable quantities, and compared them with the results of observations, and the comparisons have always been satisfactory.

He gives comparative pairs of curves, one drawn by the tide-gauge, the other calculated by the formula, and the striking resemblance is at once appreciable by the eye. The coincidence would be still nearer if the influence of the small sidereal-time variations were added.

The mean amplitudes of the four chief oscillations are as follows :—

	Millimetres.
For the oscillation of twelve lunar hours ...	103·2
For that of twelve solar hours	55·
For that of twenty-four lunar hours	130·5
For that of twenty-four solar hours	62·4

The maximum amplitudes are :—

For the oscillation of twelve lunar hours ...	132·8
For that of twelve solar hours	60·9
For that of twenty-four lunar hours	272·2
For that of twenty-four solar hours	100·2

The author shows how the variable combinations of these several elements determine and account for the peculiar phenomena observed, and he explains in what particulars the circumstances at Fiume would appear to differ from those in other places, and to give rise to special phenomena peculiar to that locality.

He further devotes particular attention to the explanation of the singular daily retardation, which he states has also been noticed by M. Aimé on the coast of Algeria, although it had been erroneously ascribed by him to the effect of the wind. The real cause he shows to be the oscillations depending on sidereal time.

The non-periodical motions of the water are caused chiefly by variations in the direction and force of the wind, and in the barometer-pressure. The temperature of the sea rain, and storms, may have also some influence, but too slight to require investigation.

The author therefore confines his attention to the wind and the pressure of the air. In regard to the former, looking at the form and position of the Gulf of Quarnero, it is evident that southerly winds will force the water into the cul-de-sac towards Fiume, and so will raise the level, while northerly winds will tend to drive the water out of the gulf, and so lower the surface.

In regard to the barometer-pressure, it is pointed out that if the weight of the atmosphere at any given part of the sea differs from that at another part some distance away, there must be a corresponding difference in the level of the water; and this difference will be proportional to the specific gravities of the two fluids :—thus a difference in the barometer of one inch of mercury will cause a difference of level of about 13½ inches in the water.

The effects of these two influences are involved in various complications, but they are sufficiently proved by the records, and their amount is shown to be considerable.

The following facts shown in the records will give some general idea of the extent of the Mediterranean tides; we believe they are pretty much the same in all parts of the sea.

The highest water level known was on Dec. 26, 1870, being 0·870 metres above a certain datum point; the lowest was on Jan. 11, 1869, being 0·482 metres below the same point. Hence the greatest difference of level experienced was 1·352 metres, or about 4½ English feet.

The average daily variation of level was 0·583 metres, or nearly two feet English; the greatest daily variation was 0·825, and the least 0·259 metres.

The mean daily variation of level is the same, whatever be the absolute general level of the water; as is natural, seeing that the latter is influenced by local circumstances that have no effect on the attractions of the sun and moon.

The mean high and mean low water stand at equal distances above and below the average mean level.

The author modestly expresses the opinion that his own three years' observations are of too limited extent to determine fully the values of all the influences which affect the tides, and he recommends that before the investigation is carried further, accurate observations should be made at other points of the Adriatic Sea, in order that, by a combination of such data, the distinction between normal and exceptional phenomena may be more positively defined. No doubt such an extended inquiry would give results of great value to physical science, and M. Stahlberger's excellent example is not unlikely to stimulate others to co-operate in such an undertaking.

The book is well got up. It is written in the national language, but there is also given a translation into German, and the data, in the form of tables, are so full and complete as to enable anyone to verify, by his own examination, the conclusions arrived at by the author.

OUR BOOK SHELF

Cambridgeshire Geology; a Sketch for the use of Students. By T. G. Bonney, F.G.S., Tutor and Lecturer in Natural Science, St. John's College. Cambridge: Deighton, Bell, and Co., 1875.)

MR. BONNEY'S short sketch of the geology of the neighbourhood of Cambridge will be a useful handbook to those students who wish to become practically acquainted with the geological features of the country round their temporary home. It makes no pretensions to be an exhaustive description, and happily is not written in a style suitable for cramming, but simply draws the attention of the careful reader to all the interesting points in connection with the geology of the district, and notices the various contributions to fact or theory made by previous writers, embodying many of Mr. Bonney's own observations. The first deposits described are the Oxford clay of St. Ives and the Elsworth rock, the true position of which latter is discussed; and then follows a notice of

the coral reef at Upware, and the Kimmeridge clay at Ely. We have next a discussion of the coprolite and associated beds at Potton and Upware, which Mr. Bonney considers Upper Neocomian, and he thinks most of the fossils derived. After a short notice of the Gault comes a full discussion of the interesting questions connected with the so-called Upper Greensand. An admirable outline of its palæontology is first given, and the origin of its phosphatic nodules is then concluded to be analogous to that of flint, or what is here called concretionary action. With regard to its age, Mr. Bonney follows Mr. Jukes-Browne in considering it homotaxial with the chloritic marl, and a large part of its fossils derived from the Upper Gault. The chalk is dismissed with a very short notice, and an account of the Post Pliocene deposits concludes the sketch. These deposits are described under six divisions, the lowest being the true Boulder Clay. The most interesting of these is the "Fine Gravel of the Plains," which has yielded so many mammalian remains. Five appendices follow: on Upware sections, the Ely pit, the Hunstanton red rock, the water supply, and building stones of Cambridge. The second of these might well have been omitted, for though it refers to an interesting case of a large chalk boulder, we are now sufficiently familiar with such instances of huge transported rocks to make it waste of time to discuss imaginary systems of impossible faults to account for its presence in some other way.

Journey across the Western Interior of Australia. By Col. Peter Egerton Warburton, C.M.G. With an Introduction and Additions by Charles H. Eden. Edited by H. W. Bates. With Illustrations and a Map. (London: Sampson Low and Co., 1875.)

COL. WARBURTON well deserves any honours which he may have received; for the sake of increasing knowledge he has performed as bold a feat of travel as is on record. With his son, Mr. J. W. Lewis, two Afghan camel-drivers, and two natives, he set out on April 15, 1873, from Alice Springs, in E. long. 133° 53′ 14″, S. lat. 23° 40′, about 1,120 miles north from Adelaide, and travelled right across the centre of the Australian continent, reaching the western side in January 1874. Col. Warburton's narrative in the book before us consists of the record which he kept day by day of his progress. The party had sixteen camels, and were provisioned for six months. Experience has shown that to explore Central Australia camels alone are of any use, horses being totally unable to bear up against the universal scarcity of water, and the bristling spinifex stalks which cover the ground almost everywhere, and which cut their legs to pieces. Col. Warburton's journal, not long after the start, becomes a painful record of a daily hunt after water, a hunt which was often unsuccessful. During the greater part of the journey man and beast were in a chronic state of parching thirst. The country crossed over is as arid and desolate a wilderness as can well be conceived, consisting mainly of low sandy hills covered almost everywhere with the above-mentioned spinifex, occasionally varied by a salt marsh, a few hills, and rarely a few trees. Indeed, the whole country from 121° to 131° E. long. is one great sandy desert. Bustards, one or two species of pigeons, owls, rats, a small species of kangaroo, swarms of torturing flies and ants, were met with, the last-mentioned with painful frequency. Natives were also seen, and they proved perfectly harmless and generally shy, and some of them Col. Warburton describes as handsome and well made.

The general method of procuring water was to scoop out wells in the sand, and it was only at long intervals that suitable places occurred. The food supplies of the party were very soon exhausted, and they had for the greater part of the journey to live on roots, an occasional "wallaby" (small species of kangaroo), and on the camels which they were compelled to kill. Of the fourteen camels, only two reached the journey's end, some having been lost, some left behind as unable to move, and seven killed for food. The flesh of the latter seems to have been as tough and devoid of nourishment as leather, and by the time the party reached the welcome river Oakover they were all nearly on the point of starvation; latterly, Col. Warburton himself had to be tied on his camel's back. On reaching the Oakover, some of the party pushed on to the settlement for relief, which at last came, and Col. Warburton met with an enthusiastic reception everywhere from Roeburne to Perth and on to Adelaide. He has made a valuable contribution to our knowledge of Central Australia, and as the spirit of exploration seems to be thoroughly aroused in the colony, we may hope soon to have its geography at last filled up. The difficulties and dangers of Australian exploration are well known, and by forethought and organisation no doubt they might be successfully met. It seems doubtful whether any economic use can ever be made of the arid wastes of Central Australia, but a thorough knowledge of its natural history and geology would be of high value from a scientific point of view. All the expenses of Col. Warburton's journey, we should say, were generously borne by the Hon. T. Eden and Mr. W. W. Hughes, public-spirited Australian colonists.

The introduction occupies about one-half of this volume, and consists of a carefully compiled and most interesting *résumé* of Australian exploration from Eyre's daring journey in 1840 downwards; it adds much to the value of the work. Mr. Bates has discharged his editorial duties satisfactorily. A good portrait of Col. Warburton is prefixed, and the map gives one an excellent idea of the route as well as of the nature of the country. The other illustrations are rude but interesting. Altogether the volume is a valuable contribution to the history of Australian exploration.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Acoustic Phenomenon

PERHAPS the following description of a phenomenon in sound which I have frequently observed may be of some interest to a few of your readers:—

If an observer is placed a short way, say about eight yards, in front of a straight palisaded fence made with deals of about three inches in width and about six inches from centre to centre apart, so as to leave intervening spaces of three inches, and then gives a smart clap with his hands, or, what is better, with two flat pieces of wood, a peculiar echo is heard almost at the same instant.

The nature of the sound is neither that of a true musical note nor of an inflection; it appears to the ear to be somewhat intermediate to those, inclining more at the beginning, when well elicited, to a very high-pitched sound of the latter kind; it slides down until it becomes a distinctly audible musical sound at the end, if the fence is 80 or 100 yards long; with those dimensions a moderately quick ear can easily recognise the pitch of the final note to be near D on the fourth line of the treble clef.

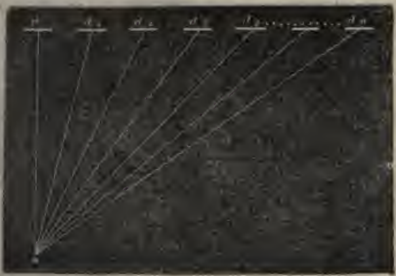
The phenomenon is caused by each board of the fence giving rise to a resonance; those aërial impulses succeed each other at constantly increasing intervals of time, and with such a degree of rapidity as to constitute a continuous sound of the kind which is here described. The vibrations will be seen, from the following diagram, to be neither isochronous like those of a musical sound, nor to vary in their periods in the same simple order as those of an inflection which is produced by sliding the bridge of a monochord while it is vibrating.

Let o be the position of the observer, and $d.d_1\ d_2\ d_3$ &c. the boards of the fence.

Call the distance $o\ d = D$, and $d\ d = \delta$. Then by the common rule for right-angled triangles the distances of each board from the observer are respectively $\sqrt{D^2}$, $\sqrt{D^2 + \delta^2}$, $\sqrt{D^2 + 4\delta^2}$,

$\sqrt{D^2+9\delta^2}$; the reflected sounds which reach the observer will travel double those distances.

$D(D^2+\delta^2)(D^2+4\delta^2)$ &c., being integral quantities, and δ positive, the series will be an increasing one; hence the first impulse which is heard is that produced by d, and the last one that by d_n.



Twice the difference between any term and that which immediately precedes it will be the length of the sound-wave corresponding to that term, and the velocity of sound per second, divided by the wave-lengths, gives the relative pitches of the different impulses.

The wave-lengths corresponding to $d\,d_1\,d_2$ &c. are—

$$2(\sqrt{D^2+\delta^2}-D);\ 2(\sqrt{D^2+4\delta^2}-\sqrt{D^2+\delta^2});$$
$$2(\sqrt{D^2+9\delta^2}-\sqrt{D^2+4\delta^2})\ \text{\&c.} \qquad (1.)$$

And calling V the velocity of sound per second, we get the relative pitches—

$$\frac{V}{2(\sqrt{D^2+\delta^2}-D)};\ \frac{V}{2(\sqrt{D^2+4\delta^2}-\sqrt{D^2+\delta^2})}\ \text{\&c.}$$

Now, if the observer removes close up to the fence, the distance D becomes an indefinitely small quantity, or zero, and the series (1) for the wave-lengths becomes $2\sqrt{\delta^2}$; $2(2\sqrt{\delta^2}-\sqrt{\delta^2})$; $2(3\sqrt{\delta^2}-2\sqrt{\delta^2})$; $2(4\sqrt{\delta^2}-3\sqrt{\delta^2})$, &c., or 2δ, 2δ, 2δ, &c.; that is, the wave-lengths are all equal, and a musical sound is heard. In practice, an ordinary fence does not yield a sufficiently loud note to be easily heard in this case, but one made with posts having intervening spaces of about five inches gives a good result when one stands four or five feet from it, the note comes out almost perfect. By taking different values for D we have from series (1) a corresponding change of wave-lengths, so that if a row of persons are placed from o to d, each will hear a sound which is different in pitch from that heard by all the others.

It is perhaps needful to state that the sound which has been described is completely masked if there are houses or a wall a few feet behind it, or if the place of observation is a road fenced with palisades on both sides, two sounds are produced which interfere and confuse each other.

Glasgow ANDREW FRENCH

The Degeneracy of Man

THE numbers of NATURE for June and July last, which have lately reached me (vol. x. pp. 146, 164, 204 and 205), contain a correspondence on the subject of the degeneracy of man, in connection with which I wish to contribute a few remarks.

I have nothing to say on the original point introduced by Mr. E. B. Tylor. But, during my residence in the islands of the Pacific, I have given some attention to the general question of degradation or progression, as exhibited in the Polynesians. The result is, that I believe there are numerous indications of the degeneracy of these people from a higher social and intellectual level than that which they at present occupy. I could not give in detail, in this letter, the entire evidence on which this opinion is based; I will therefore briefly mention two or three indications only of this degeneracy which I have noticed.

The language of the Polynesians furnishes one of these. While there is much in it which shows a low moral tone, there are, on the other hand, many refinements (a large proportion of which are known to most of the present generation) which I do not believe could have been invented, or gradually developed, by the race in its present intellectual condition. Their old traditional stories, and their ancient poetry also, are so different from anything the present Polynesians are capable of producing, that I often think (your classical readers will please pardon the comparison) the relative difference, between the past and present, is as great as that between the intellect of the Greeks, in the period of the highest Attic culture, and those of the present century. I have often asked men of more than average intelligence, why their modern compositions are so inferior to many of the old ones. They invariably reply that the men of old were greater and wiser than those of the later generations.

The industrial and ornamental works of the Polynesians are all, I believe, of ancient origin. Their houses, their canoes (with one exception), their fine mats, the way in which they make their bark cloth, and even the patterns which they print on it, are all according to the traditional forms handed down from generation to generation. There is no originality. Invention is unthought of. Even now, when the influence of external civilisation is brought to bear with considerable force upon them, they adopt a new idea very, very slowly. If they had never been in a higher and more active intellectual condition, I cannot conceive how they could possibly have obtained the many comparatively excellent customs, the—in many respects—elaborate language, and the advanced social customs which were in their possession when first they became known to the civilised world.

I am well aware that absolute proof of the degeneracy of the Polynesians will not, by any means, render necessary the conclusion that degeneracy has been universal with the human race. Advocates of the progressive theory do not deny that some instances of degradation are to be found. In his "Primitive Culture" (vol. i. p. 34) Mr. Tylor says: "Of course the progression-theory recognises degradation, and the degradation-theory recognises progression, as powerful influences in the course of culture." Hence I present the indications of degeneracy above-mentioned as, at most, only a minute portion of the cumulative evidence which must be adduced indisputably to prove the degradation-theory of general application to the human race.

Apropos of this question I may add, that I often think much of the difference between (at least the more moderate) progressionists and degradationists is owing to the want of a clear definition of the term *civilisation* as used on either side. One appears to me to think chiefly of a *material civilisation*, while the other thinks mainly of a *moral civilisation*. I do not believe in the evolution of man from a lower form of life. But, notwithstanding this, I doubt whether the first man was *civilised* in the ordinary sense in which that word is now used. So far as a material civilisation goes, I take him to have belonged to the earliest stone age. But at the same time I feel the strongest conviction that he was, in point of moral civilisation, immeasurably in advance of a savage. It has often been said by advocates of the degradation-theory that no well-authenticated instance has ever been given of a savage who has, apart from external help, improved his condition. I believe this assertion to be true, notwithstanding Sir John Lubbock's "Cases in which some improvement does appear to have taken place," given in the appendix to his "Origin of Civilisation" (pp. 376-380). I do not deny the force of the reply to the above assertion, given by advocates of the progression-theory; viz., that it is almost impossible to *prove* that a savage race has, unaided by external influence, bettered its condition. But from personal observation of savage and semi-savage life, I feel almost certain that a real savage is utterly incapable of, in any way, raising himself. He lacks the sensibility which must serve as a fulcrum for the lever which is to lift him. Upon this ground alone, if I had no other reason for it, I should doubt whether man had, unaided, developed himself from a state of unmitigated savagery.

Upolu, Samoa S. J. WHITMEE

The Law of Muscular Action

IN NATURE vol. xi. p. 426, my esteemed friend Prof. Hinrichs does me the honour to comment on my paper published in NATURE, vol. xi. pp. 256 and 276.

He claims to have found that in lifting a weight w until exhaustion sets in, the number of lifts n is represented by the equation—

$$\left.\begin{aligned} n &= \frac{A}{B^w} \\ \text{or}\quad \log. n &= \log. A - w \log. B \end{aligned}\right\} \qquad (1)$$

where A and B are constants.

That the relation between n and w (the strength of the muscle

remaining constant) is a logarithmic function was plainly indicated in the last paragraph but one in my second paper in NATURE, p. 277. In my paper in the *American Journal of Science*, Feb. 1875, p. 130, a formula was given at the close of the paper, p. 137, which is equivalent to Hinrich's formula (1), calling τ the time of exhaustion (or number of lifts), and s the strength of the muscle obtained with a dynamometer, and

$$\tau = a(s - \beta)^v \qquad (2)$$

where a and β are constants. If the dynamometer gave the real strength in kilograms, β would equal w. In the series published in NATURE, s was obtained in another way, there described, and β was zero (nearly); v is a function of the weight. So that Hinrichs' formula does not seem to differ essentially from (2). In giving this formula, I stated expressly that I did not wish to discuss this equation at present, as the constants had not been determined with satisfactory precision. I take this occasion to repeat that statement.

Another point to which it may be well to call attention is, that in exhausting the arm with heavy weights very little pain is felt. With light weights, however, the pain is very great.

Our knowledge of this whole subject is yet so fragmentary, and the subject itself is so complex, that we can only hope to represent our knowledge by empirical formulæ. The best service is to be rendered in the direction of careful experiment. I shall therefore devote a few years to the work outlined in my paper in the *American Journal of Science.*

Washington University, St. Louis, Mo., April 28 — F. E. NIPHER

Physiological Effects of Tobacco Smoke

Is Dr. Krause (NATURE, vol. xi. p. 456, vol. xii. p. 14) acquainted with the manner in which cascarilla bark modifies the physiological effects of tobacco smoking? The addition of a few very small fragments of the bark can hardly be supposed to materially affect the amount of carbonic oxide produced; and yet, with such an admixture, the strongest tobacco may be smoked by a tyro without, in most cases, the production of the usual nauseating effects. Loss of appetite, thirst, vascular and nervous depression are sometimes produced if such a mixture is smoked in excess. On the other hand, if Dr. Krause's theory, that the nausea, &c., of tobacco smoking is due to the carbonic oxide inhaled, be admitted, the question is suggested whether some of the volatile products of burnt cascarilla bark are antagonistic in their physiological action to the gas in question? C. E. S.

OUR ASTRONOMICAL COLUMN

NEW VARIABLE STAR (?).—Mr. J. E. Gore, of Umballa, writes with reference to a star of about the 6th magnitude noticed on the 13th of January about 1° north, following θ Leporis, and not having found it in Harding's Atlas or in Lalande, or the B. A. C., he supposed it might be a new star. "It is of a reddish colour, and is in the same low-power field with, and about 25′ north of (a little preceding) the 7m. star Lalande 11778 . . . It is closely followed by two small stars which formed with it a curved line." From this description the star is evidently VI. 58 of Weisse's first Catalogue, observed by Bessel early in 1825, and estimated 6·7 magnitude, the small stars preceding it being Nos. 68 and 78 of the same hour. It is not found in D'Agelet, Lamont, or in any other catalogue we have examined, of previous date to that accompanying Heis's Atlas, where it is entered 6·7, but erroneously identified with VI. 78 of Weisse's second Catalogue, instead of VI. 58 of his first. (The large number of similar errors in Heis's references is a serious defect in a work otherwise of so much value.) Mr. Gore mentions that he had not remarked, up to the middle of April, any variation in the star's light, but it evidently requires further examination, and may yet appear on our rapidly extending list of variables.

THE BINARY STAR ζ HERCULIS.—If good measures of this star are obtained during the present season, we may expect to know the elements of the orbit with considerable precision. Dunér's results, founded upon measures 1826–69, will be the best so far published, but he did not regard them as definitive; they will no doubt be very useful in any further investigation, and for this reason are here subjoined:—

Peri-astron passage 1864·23

Node	45° 56′	Excentricity ...	0·42394
Node to peri-astron on orbit ...	250 50	Semi-axis ...	1″·223
		Period	34·221 yrs.
Inclination ...	34 52		

PETERS' ELLIPTIC COMET 1846 (VI.).—This comet, which was detected at Naples on the 26th of June, 1846, by Dr. Peters, now Director of the Observatory at Clinton, New York, was calculated by Prof. D'Arrest, and in a more complete form by the discoverer himself, who, in a memoir published in the Transactions of the Naples Academy in 1847, found the time of revolution 12·85 years, but with an uncertainty of ± 1·61 years; in a subsequent communication to Brünnow's *Astronomical Notices*, he gave elements for 1859, including the effect of perturbations of the planet Saturn, which, however, he shows to be liable to very considerable doubt, on account of the observations in 1846 being insufficient to fix the mean motion at perihelion in that year within narrow limits. It is to be remarked that in 1846 the comet appeared under nearly the most favourable circumstances possible for observation, and at the time of discovery the comet was distant from the earth less than 0·6 of our mean distance from the sun, yet Dr. Peters found it very small and faint, and unless the perihelion passage should happen to fall about the same time of the year as in 1846, it might be exceedingly difficult, if not impossible, to recover it. The only hope of doing so is in keeping a close watch in the late spring and early summer, upon those parts of the sky indicated with different suppositions for date of perihelion passage, say from May 15 to June 15, which are wholly in south declination, a circumstance that will render the assistance of observers in the other hemisphere very desirable. To give an idea of the comet's track in the heavens when the perihelion falls in May, we assume the 15th and 25th for the passage by this point of the orbit, and thus have the following positions:—

	In perihelion, May 15·0.			In perihelion, May 25·0.		
	R.A.	Decl.	Distance	R.A.	Decl.	Distance
May 15...	256°·5	50°·0 S	0·594	228°·8.	55°·8 S	0·600
„ 25..	256 ·5	42 ·2	0·552	231 ·1	48 ·4	0·561
June 4...	255 ·9	32 ·8	0·538	233 ·4	39 ·2	0·546
„ 14...	255 ·3	23 ·1 S	0·555	235 ·8.	29 ·4 S	0·564

The least distance between the orbits of the earth and comet is about 0·53.

Considering the uncertainty in the mean motion deduced from observation in 1846, it is quite within possibility that a perihelion passage may occur as late as the summer of the present year, and it may be worth while to institute a search upon that supposition.

MINOR PLANETS.—No. 26, *Circular zum Berliner Astronomischen Jahrbuch*, just issued, contains new elements and an ephemeris of No. 114, Cassandra, and corrected ephemerides of No. 71, Niobe, and No. 128, Nemesis. The period of revolution assigned to Cassandra for November 1872 is 1598·5 days. Several of this group are now adrift, the elements not having been determined with sufficient approximation to keep them in view. The planet found by Borrelly at Marseilles, 1868, May 29, and that detected by Pogson at Madras on November 17 in the same year, are thus situated; both travel beyond the limits of our ecliptical charts, which contain very small stars.

OUR BOTANICAL COLUMN

THE PANDANEÆ.—A fine series of Pandanus fruits has recently been received at the Kew Museum from Mr. John Horne, of the Botanic Garden, Mauritius

These fruits form the first consignment of a quantity collected in Mauritius and Seychelles by Mr. Horne for transmission to Kew, as material for the *Pandaneæ* in the forthcoming Mauritius Flora, and will form a valuable addition to the Museum collection. The fruit-heads of the *Pandaneæ*, like the cones of the *Piceas*, are very difficult to preserve entire except they be kept in fluid, and even then, if they are gathered too ripe the single drupes are apt to separate from the central axis. Those just to hand from Mr. Horne are the best set ever received at Kew, inasmuch as they appear to have been carefully selected and gathered before they were too ripe, wooden tallies with numbers *cut* in them firmly fixed upon each specimen with copper wire, and the whole sown up tightly in stout sacking or canvas and placed at once in rum. In this way the collection contained in five small barrels arrived in perfect safety at Kew, where the specimens, after being taken from the spirit and the canvas coverings cut away, were securely enclosed either in a network of thin copper wire or fine strong cord and gradually dried. We mention these facts because travellers and collectors too frequently send home specimens of Conifers, Cycad cones, or others of a similar nature simply rolled in paper or packed in sawdust; in the one case they dry and fall to pieces immediately upon opening, while in the other the sawdust absorbs moisture, and the fruit or cone simply rots and becomes quite worthless. Another advantage in sending woody fruits like the *Pandani* in fluid in the manner above described, is that they can be removed, dried, and mounted on wooden stands, by which they are more convenient for examination, and occupy much less space, and are manifestly more economical both for public and private collections than when preserved in large glass jars in alcohol. The collection, numbering some twenty-three heads of fruits, sufficiently illustrates the variety of form and size in the different species, the largest being some thirteen inches through, and the smallest not more than two inches. Mr. Balfour, who accompanied the Transit of Venus Expedition to Rodrigues, has also paid special attention to the *Pandaneæ*, and his collections, preserved, we believe in a similar manner, have recently arrived in this country.

SANTAL VERT.—Under the name of *Santal Vert*, or false sandal-wood, a dark green, close-grained wood, somewhat like *Lignum vitæ*, may occasionally be seen in wood collections. The origin of this wood is not generally known, but it seems to be the produce of an Euphorbiaceous plant, probably a species of *Croton*. The bulk is obtained from Madagascar, and some from Zanzibar. It is generally supposed, however, to be the produce of Zanzibar, probably on account of that from Madagascar passing by way of Zanzibar in course of transit to India, to whence it is mostly shipped, chiefly, it is said, for the purpose of burning the bodies of Hindoos, as it fetches a much lower price than the true sandal-wood. The wood of the *Santal Vert*, though small, is sometimes used in Mozambique for furniture. A species of *Croton* found by Dr. Kirk on the Zambesi produces a similar wood; indeed, it may be identical.

SOME RESULTS OF THE "POLARIS" ARCTIC EXPEDITION

IN a letter to the French Geographical Society, published in the March *Bulletin*, Dr. Bessels, the principal scientific member of the *Polaris* Arctic Expedition, rebuts some of the statements published by Mr. Tyson, and gives some of the scientific results which were obtained. The position of the Observatory, obtained from many varied observations, was 81° 38′ N. lat., 61° 44′ W. long., and thirty-four feet above sea-level. Many careful observations were made on the tides, in meteorology, magnetism zoology, botany, geology, and with the pendulum, in order to determine the force of gravity. Unfortunately, in the catastrophe which happened to the ship, many of the results of these observations were lost; nevertheless, enough was saved to afford a fair idea of the physical geography, the geology, the fauna and flora of the region visited. Dr. Bessels is preparing a detailed account of the results obtained, and we believe has given much valuable information for the use of our own Arctic Expedition.

The pendulum observations are specially precise and valuable. The magnetic observations are more complete than any hitherto made in the polar regions. The observations on declination were made every hour for five months, and during three days in each month every six minutes. The western declination was found to be 96°, and the absolute declination 84° 23′.

The observations on the tides were made with very great care, generally every hour, and for three or four weeks every ten minutes, in order to obtain the precise moment of the flux and reflux. High water occurs about every 12h. 13m.; the highest flux observed was 8 feet; the lowest reflux, 2·5 feet; mean of high and low tide, 3·8; mean of spring tide, 5·47; mean of neap tide, 1·83. Other hydrographical observations comprehend soundings, temperatures at various depths, and detailed observations on the specific gravity of the water.

After having entered Smith Sound, a current was observed running southwards, the rate of which varied from 1·5 to 5 miles. This current carried with it much driftwood, all the specimens of which seen by Dr. Bessels were coniferous, with very close ligneous layers, indicating that the specimens came from a cold climate.

The greater part of the meteorological registers were saved, embracing observations on the temperature of the air and on barometric oscillations, anemometric and hygrometric results, observations on terrestrial and solar radiation, on polar auroræ, and on ozone.

The fauna and flora of Hall's Land are very rich, but unfortunately nearly all the specimens collected were lost. Eight species of mammals were observed, twenty-three kinds of birds, fifteen species of insects, and seventeen species of plants. Of the mammals, *Myodes, spr.* (Pallas) and *Ovibos moschatus* (Zimm.) were found in West Greenland for the first time. The greater part of the insects are Diptera, of which one species is new.

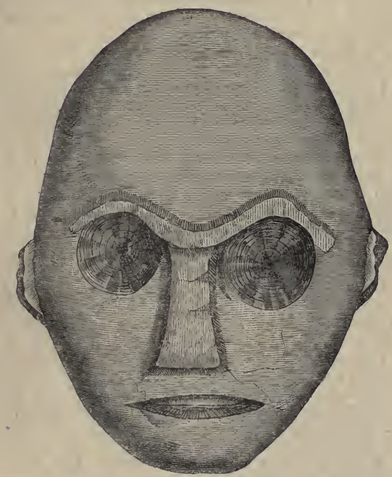
Although the geological formation of Polaris Bay and its neighbourhood presents only Silurian limestone, containing few fossils, yet some very interesting observations were made. At elevations of 1,800 feet, not only was driftwood found, but also shells of molluscs (*Mya*, &c.), of species which still exist in the neighbouring seas. On examining some of the small lakes which abound in the region, marine crustaceans were found to be living in these fresh waters. This is certain evidence of the gradual elevation of the coast of this part of Greenland.

Wherever the country is not too steep, large numbers of erratic blocks are met with, of a kind quite different from the rocks on which they rest. There are blocks of granite, gneiss, &c., from South Greenland, and these blocks have evidently been borne, not by glaciers, but by floating icebergs; a proof that at one time the current in Davis Strait had a different direction, and passed from south to north. Dr. Bessels believes that Greenland has been separated from the American Continent in a direction from south to north.

ON THE OCCURRENCE OF A STONE MASK IN NEW JERSEY, U.S.A.

THE occurrence of stone "masks," such as the specimen referred to, has been somewhat frequent, in and about the "mounds" of the Ohio and Mississippi Valleys, but not eastward of these localities. Somewhat more

elaborate carvings of the human face have been found in Western New York, figures of which are given in the Thirteenth Annual Report of Regents of New York State University. These may or may not be of identical origin with the western mound specimens. The specimen here figured is, I believe, the only one ever found in New Jersey. It is a hard sandstone pebble, such as are common to the bed of the Delaware River, above tide water. It measures six inches in length by a fraction over four inches in greatest breadth. It is concavo-convex, the concavity being shallow and artificial. The carving of the front or convex side is very rude, but shows distinctly that it has been done with *stone tools* only. The eyes are simply conical counter-sunk holes, rudely ridged, and just such depressions as the stone drills, so common among the surface relics of this neighbourhood, would produce. In the collection of stone implements from Central New Jersey, at the Peabody Academy of Salem, Mass., are several drills sufficiently large to bore as wide and deep depressions as the "eyes" of this mask. The nose is very flat and angular; the mouth merely a shallow groove. The ears are broken, but appear to have been formed with more care than any other of the features. The chin is slightly projecting.



The interest attaching to this specimen is, I think, twofold, and worthy of a moment's consideration. It is interesting from the fact of being found in New Jersey, a point much further east than the mound-builders have been supposed to reach, and there is no reason to suppose that the specimen was ever brought by white men from the west, and lost here. The circumstances connected with its discovery render such a supposition untenable. Its interest, otherwise, is in the fact (as I suppose it) of its being a true relic of the mound-builders. The mystery of this people has certainly yet to be solved, if, indeed, it ever can be, and the relationship they bore to the "Indian" determined. In the prosecution of my investigations into the "stone-age" history of the New Jersey Indians, I was continually struck with the great resemblance of the stone-implements found in New Jersey to those found in the western mounds. The specimens figured by Messrs. Squier and Davis, in the first vol. of Smithsonian Contributions, 1847, were all, or nearly so, duplicated by specimens I gathered in New Jersey; and up to the time of the completion of my second paper on the Stone Age of New Jersey (now in press), I needed but "animal pipes" and stone masks, such as the above, to make the duplication of the mound-relics complete. The occurrence of this specimen brings it to the one form of pipes, and that such have occurred in New Jersey is highly probable; but not having gathered such a specimen, myself, I assume that none have yet been found. It must be borne in mind, however, that as there are no mounds in New Jersey, animal pipes, if found here, must occur as surface relics, or in graves; which latter were, as a rule, very shallow. As New Jersey has been settled for about two centuries, it is probable that such animal pipes would be gathered up, when found, and soon again lost or destroyed, when ordinary "relics" would be overlooked. In this way, such animal pipes would have all disappeared, perhaps a century ago, when their value as archæological specimens was unknown. This, too, might account for the great rarity of such specimens as the mask here described.

CHAS. C. ABBOTT

Trenton, New Jersey, U.S.A., April 22

FERTILISATION OF FLOWERS BY INSECTS *

X.

Lilium Martagon.

C. SPRENGEL was the first to turn his attention to the structure of the beautiful flowers of this plant; † but he did not succeed either in observing insects visiting them or in explaining the contrivances by which they are cross-fertilised when visited by suitable insects. Since Sprengel's time nobody had, as far as I know, studied the manner of fertilisation of *Lilium Martagon.* It was, therefore, with great pleasure that, in Thuringia, I examined the structure of its flowers, and watched them in their natural habitat. The results of my observation were as follows.

Along the middle of each sepal and petal, beginning at its base and continuing throughout a length of 10-15 mm.,

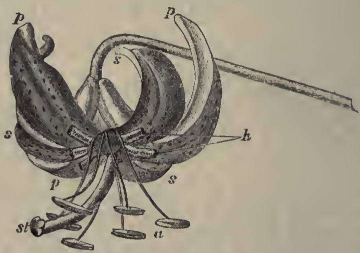


FIG. 63.—Flower of *Lilium Martagon* in its natural position and natural size.

is a furrow, which secretes honey, and whose margins converge and are bordered with reddish knobbed hairs, so close as to cover the open side of the furrow, and to convert it into a channel (*h*, Figs. 63, 64). The basal opening of this channel (*b*, Fig. 64) being closed by the base of a filament, the only way by which the honey is attainable is the small opening at the end of the channel (*e*, Fig. 64). This opening, as well as the channel itself, is very narrow, its diameter only a little exceeding 1 mm. No other insects except Lepidoptera are provided with sucking instruments sufficiently long and slender to be able to reach the honey concealed in these long and narrow channels; and from the flowers being turned downwards and the stamens projecting and slightly bending upwards, it is evident that Lepidoptera, when sucking this honey, cannot avoid dusting their under-side with pollen, and effecting cross-fertilisation as often as they fly to another

* Continued from vol. xi. p. 171.
† C. Sprengel, "Das entdeckte Geheimniss," &c., pp. 187–189

flower and bring their pollen-covered under-side first in contact with the stigma, which slightly overtops the anthers. The flowers of *Lilium Martagon* must consequently be considered as adapted to cross-fertilisation by Lepidoptera.

The colour of these flowers, dark reddish brown, with dark purple dots on the inside, is not very striking, and in the daytime they are but slightly scented, whereas during the evening they emit a very attractive sweet odour. Hence we may safely conclude that they are far more attractive to crepuscular and nocturnal than to diurnal Lepidoptera.

Thus far, in Thuringia, in July 1873, I had succeeded in explaining the separate peculiarities of the flowers; but in vain had I watched them repeatedly during the evening in order to surprise the fertilisers in the very act of fertilisation. But the hope I had failed in when making every effort to realise it, happened to be fulfilled a year later, quite unexpectedly. In the Vosges, returning from the Hoheneck, and passing the village Metzerall, July 5, 1874, towards the evening, I was struck with the sight of flowering plants of *Lilium Martagon* growing in a garden hard by, and a specimen of *Macroglossa stellatarum* flying round them and fertilising them.

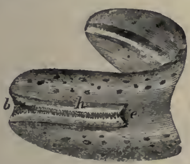

FIG. 64.—A single sepal or petal of this flower, magnified.

Freely fixed in the air by the rapid movement of his wings, this busy Sphinx inserted his long slender proboscis into the honey-channels of the sepals and petals, now of a single one, now of others of the same flower, and having done so immediately flew away to another flower. Yet, the flowers never being turned directly downwards, but somewhat inclined, all the honey-channels of any flower were never sucked by the Sphinx, but in every case only those of the uppermost sepals and petals. When sucking he always touched the stigmas and the anthers with his legs and under-side, and the latter ones were to be seen rocking and swinging. Thus, undoubtedly, the under-side of the Sphinx was dusted with pollen, and the stigma of the flower next visited, when first touched by the pollen-covered under-side, was cross-fertilised. A single Sphinx, with his vehement movements during a quarter of an hour, may easily visit and cross-fertilise plenty of flowers of *Lilium Martagon*. Nevertheless, self-fertilisation in many of these flowers will occur, where visits of Sphingidæ are wanting. For the stigma, by being bent upwards more decidedly than the anthers, comes frequently into contact with one or two of them; and C. Sprengel, who enclosed the yet unopened flowers of *L. Martagon* in a net, thus excluding all insects except some ants (and perhaps Thrips), was surprised to find that every capsule developed and matured its seeds.

Lippstadt HERMANN MÜLLER

NOTE ON THE HYRCANIAN SEA

THE resolution of the problems which are involved in the physical aspects of Western Turkestan, and which have offered so ample a scope for speculation, will probably be one of the earliest and most important consequences of the occupation of the banks of the Amú Darya by Russia. But, whatever may be the light which will thus be afforded to geographers, ethnologists, or historians, it is to be expected that the field of inquiry will widen and recede, in proportion as each step forward is made, along paths which have hitherto been shrouded in obscurity.

Among the observations which will demand, and which will most certainly fully repay, the greatest attention, are those which shall accurately determine the true rate of evaporation from the surface of Lake Aral. A meteorological observatory was established in June 1874 on the lower courses of the Amú, and its working will contribute much to a knowledge of the rate of local evaporation. It may be doubted, however, whether such observations as are recorded at Núkús will be of practical value for determining the desiccation going on in Lake Aral itself. In the absence of precise information we shall for some years be dependent upon data of doubtful trustworthiness, in regard to the aspect the lake may have presented at different epochs in past history.

Among such data there is an isolated observation which seems worthy of more attention than has hitherto been given to it. Between the years 1848 and 1858 Boutakoff found that the depth of water at the entrance of Abougir (the gulf at the south-west corner of Lake Aral, which is now entirely dry) had decreased by eighteen inches, or, in other words, at the rate of 0·05 yards per annum. This rate of decrease may possibly be not very exact; but it is approximately so, and may therefore serve, until better data are available, to draw some conclusions regarding the Aralo-Caspian Sea.

The chart of Lake Aral, compiled from the surveys of 1848-49, shows the waterspread to be about 24,500 square miles. The contour line drawn at a depth of twenty-four feet on this chart includes an area of about 18,300 square miles, *i.e.* the loss of surface is 6,200 square miles. For every yard of fall below its surface of 1848, Lake Aral, down to a depth of eight yards, loses a waterspread of 775 square miles. And since during the past twenty-seven years the surface has fallen $27 \times 0{\cdot}05 = 1{\cdot}35$ yards, the waterspread of 1875 will be $24500 - 775 \times 1{\cdot}35 = 24500 - 1046{\cdot}25 = 23453{\cdot}75 = 23454$ square miles, say. The mean of the two waterspreads of 1848 and 1875 will be $\frac{24500 + 23454}{2} = \frac{47954}{2} = 23977$ square miles, or 74,271,155,200 square yards; and this quantity multiplied by 0·05 gives 3,713,557,760 cubic yards as the volume of water lost by Lake Aral yearly since 1848, or a loss of 120 cubic yards per second.

The supply poured into Lake Aral by the Amú and by the Syr can only be guessed at, since it has probably fluctuated during the past twenty-seven years. At the present time the combined volume afforded by those two rivers may be taken at about 2,000 cubic yards per second; and this estimate is probably not ten per cent. removed from the actual truth. The evaporation, then, from the lake must be assumed to have been, since 1848, $2000 + 120 = 2120$ cubic yards per second, from a waterspread of 23,977 square miles, or 74,271,155,200 square yards, which is equal to an evaporation of 0·0026 yards per diem = 0·0936 inches per diem, or thirty-four inches per annum.

The physical aspects of the shores of Lake Aral suffice to show that in very recent times its level has been at least fifty feet higher than that of to-day. With this increased depth the waterspread would be about 36,500 square miles, or 113,062,400,000 square yards. The daily evaporation from this surface at 0·0026 yards will be 293,962,240 cubic yards, or 3,400 cubic yards per second. There was therefore a time (and that a recent one) when Lake Aral received a supply of 3,400 cubic yards per second; and, indeed, of more than that quantity. The Russian knowledge of the country, handed down by the great map of the sixteenth century, informs us that a river flowed from the Aral to the Caspian. The geographical MS. of (according to M. Vámbéry) Ibn Said el Belkhi, notices in the early part of the tenth century, the opinion that the two seas communicated; and this com-

munication could, and almost certainly did, take place in the following way.

The crest of the spur of the Ust Urt plateau, which formed the southerly limit of the now desiccated gulf Abougir, is about fifty feet above the present level of Lake Aral. Once filled up to that level, if the lake continued to receive more water than was evaporated from its surface, *i.e.* more than 3,400 cubic yards per second, an overflow would take place into the country now traversed by the channel called Uzboy, which has a gentle slope to the south of less than four inches per mile.* It is probable that the lands stretching from Uzboy westwards to the foot of the elevations encircling Karaboogas would have been flooded. Perhaps at this high level Aral may have discharged at its extreme north-western point also, and have flooded the country stretching round the northern foot of Ust Urt. On the north, it may have topped the low transverse ridge which now divides the northern and southern drainage. And if, in addition, the level of the Caspian was at that time some few feet higher than it now is, its waterspread would have advanced to meet the overflow from Aral, and Ust Urt and its narrow southern spurs, which run along the east shore of the Caspian, would have been isolated among marshes and shallow water. The classical geographers would thus have had ample grounds for the description they have handed down to us of the Sea of Hyrcania, as well as good reason for giving but a single name to the waterspread of the sea, since the separation of its basin from that of Aral would have become evident only after the fall of the level of this lake.

Until the separation became evident, this Aralo-Caspian Sea would have presented all those aspects which history tells us it has had. As the level gradually fell in Lake Aral, the inundated ground would become dryer; and in the first century of our era, as reported by the Chinese, the banks of the "Western Sea" would have been surrounded with great marshes. It may be doubted whether the Palus Oxiana of Ptolemy and the Oxian Marsh mentioned by Ammianus Marcellinus should be placed in this locality; but there is more probability that the Sinus Scythicus of Mela is identical with Lake Aral and its former southern marshy appendage, of which Uzboy is the axis.

The waterspread of such an Aralo-Caspian Sea would have added an area of about 70,000 square miles to the limits of the Caspian of to-day; and the evaporation from such a surface would have absorbed a supply from the rivers then feeding Lake Aral of about 7,000 cubic yards per second; in other words, a volume of water three-and-a-half times greater than that discharged by the mouths of the Amú and the Syr together at the present time.

If it be considered that at this epoch the greater, if not indeed the entire volume of the Oxus passed directly westwards into the Caspian, the difficulty is somewhat increased in finding an answer to the important question, where the large volume of water mentioned came from?

However, it is very probable that the Tchuy and the Sary Su discharged at that time into Lake Aral, instead of losing themselves, as they now do, in the sand. The Kenderlik of the great Russian chart, as well as the Demous, the Baskatis, and the Araxetes of the classics, together no doubt with many other minor streams, have disappeared in these countries, though their waters formerly would have fed Aral. Their disappearance seems to have been contemporaneous with the desiccation of the Oxus branch of the Caspian, at an epoch when those irruptions of Mongol hordes from the north-east were taking place, which swept away early Central Asian civilisation, and which subsequently caused the destruction of the Greco-Bactrian Monarchy. Whether this ruin of ancient social culture was accompanied by the destruction and wreck of a system of hydraulic works which were necessary for the cultivation of the soil, is a question whose answer possibly bears very nearly on the causes of the desolation which Nature now wears in the countries of Western Turkestan.

HERBERT WOOD

* See NATURE, vol. xi. p. 231.

THE COMMONS EXPERIMENTS ON ANIMALS BILL

THE Bill for the prevention of cruelty in experiments on animals, made for the purpose of scientific discovery, prepared and brought forward by Mr. Lyon Playfair, Mr. Spencer Walpole, and Mr. Evelyn Ashley, is of a very different character from that introduced by Lord Hartismere in the House of Lords and commented on in our last issue (NATURE, vol. xii. p. 21). In it no legislative interference is proposed in the case of operations performed for scientific purposes under the influence of anæsthetics, provided that the insensibility is continued throughout the experiment; immediately after which the animal is to be killed if it has been in any way seriously injured. In the case of operations performed on animals in which it is impossible to employ anæsthetics, it is proposed that those who wish to conduct them shall be required to obtain a license authorising their undertaking them, to obtain which from the Secretary of State a certificate must be produced signed by one at least of the following persons, viz.: the President of the Royal Society, or the Presidents of the Royal Colleges of Physicians or Surgeons of London, Edinburgh, or Dublin; and also by a Professor of Physiology, Medicine, or Anatomy in Great Britain. In the case of the applicant being himself one of the just-named professors, or an authorised lecturer on the same subjects, such a certificate is not to be required, but in its place his application would have to be signed by the registrar, president, principal, or secretary of the university or college with which he is connected. The license requires renewal each five years, except in the case of professors, with whom it lasts during their tenure of office. It extends to any person assisting the holder of the license, provided that the person assisting acts in the presence and under the direction of the holder of the license.

The penalty proposed for any contravention of the Act is a fine not exceeding fifty pounds, or imprisonment for a term not exceeding three months.

The whole tenour of this Bill is so much in accordance with our own feelings that we can say nothing against it. Physiological operations on the lower animals, when conducted under the full influence of anæsthetics, cannot shock the most sensitive-minded; and supposing the Bill passes, it will be in the power of all to see that nothing of a painful nature is undertaken. No definition of what is meant by pain is given, it is true; and the only improvement we can suggest is that one be added which prevents the employment of curare as an anæsthetic until its pain-killing power is demonstrated.

BALLOONING AND SCIENCE

THE number of aëronautical ascents in France has been greatly increased since the *Zenith* catastrophe attracted public notice to aërial questions. On Sunday, the 9th of May, not less than three different balloons went up in different places.

These ascents took place at Ivry, close to Paris, at 5.30, at Nantes at 5.40, and at Algiers at 3.45. In the three cases the balloonists experienced a change in the direction of the wind, varying greatly with altitude. The general direction of the Nantes balloon was south-east. The Paris balloon had a less velocity with a greater number of circuits, having ultimately run a distance of ten miles in two hours. The greatest velocity of the air was in close vicinity to the earth; this is an indication of a special current probably pro-

duced by the warming action of the sun on the solid surface exposed to its rays. These special currents, although somewhat dangerous in making a descent, die out at an altitude of a few hundred feet. The superficial current experienced in the Algiers ascent was running eastwards, and was really a marine current produced by the vicinity of the sea. A peculiarity of this ascent was the presence of a fog, observed at a certain distance above the earth, in air which was coming from the water and had been rendered humid when crossing the Mediterranean Sea. The thermometer, which was only 23° centigrade on the ground, ascended gradually to 25°, and gave 38° and 40° when the balloon had traversed the fog. The maximum observed was 43° at a small altitude.

Clouds do not always prevent the rays of the sun from warming the atmosphere below to a certain extent. In an ascent executed at Avignon (Vaucluse) on the 6th, the thermometer exhibited a warming effect of 5° C., although the balloon had not passed through the clouds, which were at an elevation of more than 4,000 feet.

I do not think we should depend entirely for our knowledge on such points to elaborately organised ascents. As much of our knowledge of the sea has been obtained from the log-books of trading vessels, so by a little good management on the part of aëronautical societies, much important information concerning the atmosphere might be collected from balloonists who make ascents either for purposes of pleasure or profit.

W. DE FONVIELLE

NOTES

M. ANDRÉ, the head of the French Transit Expedition to New Caledonia, has arrived in Paris. His account of the observations will be read to the Academy on Monday week. Dr. Janssen is not expected to arrive in Paris before the 10th of June.

DR. HOOKER was present at Monday's sitting of the Paris Academy of Sciences, of which he is a correspondent in the section of Botany. M. Frémy, the president, noticed the fact, and Dr. Hooker was warmly received by all present.

WE remind the Fellows of the Royal Society of the Reception on the 26th inst., at their rooms in Burlington House, to which they have been invited.

INFORMATION has been received at the Admiralty, by telegram, stating that the *Challenger* will not visit Vancouver Island as intended, but will proceed to Nagasaki, Honolulu, and Valparaiso. Letters should be addressed to Honolulu until the middle of July, and after that date to Valparaiso.

THE French Aëronautical Society has elected for its president M. Paul Bert, the physiologist, who recently organised the fatal *Zenith* expedition. M. Bert has never ascended in a balloon, and has refused several times to do so. M. Tissandier, who had experienced so narrow an escape in the *Zenith*, was appointed one of the vice-presidents.

THE Spectacle Makers have resolved to confer the freedom of their Company on Sir George B. Airy, K.C.B., F.R.S., &c., Astronomer Royal.

WE learn from the Australian papers that an expedition for the exploration of New Guinea is being fitted out by Mr. Macleay, a wealthy citizen of Sydney. Important scientific results are expected to be gathered by this expedition, and Mr. Macleay is worthy of praise for devoting his wealth to so important an object. Notwithstanding that so many explorers are and have been on the island, there is a great deal yet to be done ere we can have anything like an adequate knowledge of its people, its physical condition, and natural history. We hope Mr. Macleay's expedition will attack a part of the island not hitherto explored, and add much that is new and valuable to our knowledge of a country so interesting in itself and in relation to the past of Australia.

THE Swedish Arctic Expedition to Novaya Zemlya, which will start at the beginning of next month from Tromsöe, will be occupied first with botanical, geological, and ethnological inquiries in the southern part of Novaya Zemlya, and then advance along the west coast to the northern point, which it expects to reach about the middle of August. Thence it will go to the north-east to explore this still quite unknown part of the Polar Sea, and then southwards to the mouths of the Obi and the Jenisei, where the country is geologically very interesting. If the ice creates no obstacles, Prof. Nordenskjold will here quit the vessel, and go in a boat up the river, to return home afterwards by land.

THE February number of the *Proceedings* of the Asiatic Society of Bengal contains the President's Address. Colonel Hyde, among other important and interesting topics, refers to the scheme for providing Calcutta with a Zoological Garden, which, through various untoward circumstances, has been hitherto frustrated. The value of such an institution in Calcutta, if put on a rational footing, both to the European and native communities as well as to science, is undoubted, and we hope with Colonel Hyde that the scheme will have the attention both of the Imperial and Local Governments. Indeed, we believe that the Lieutenant-Governor of Bengal has taken up a piece of land suitable for the purpose. The question of the establishment of a Zoological Garden at Calcutta has been before the public and the Asiatic Society from time to time during the last thirty-five years, and it does seem strange that the capital of India should have been so long without such an institution.

ANOTHER subject referred to by the President in the above address is that of earth-current measurements, a committee in connection with which has been appointed at the suggestion of Mr. Schwendler. Considering the very great importance of research in this direction, "there can be no doubt," to quote the Calcutta *Englishman*, "that the Government of India would be fully justified in promoting the undertaking, just as it has assisted the observations of the Transit of Venus, of eclipses, and of meteorological phenomena."

AN unprecedented contest has taken place at the Académie Française in filling the seat vacated by the recent demise of M. Guizot. After four scrutinies, the election was postponed for six months. M. Dumas, the perpetual secretary of the Academy of Sciences, was a candidate, and had as an opponent M. Jules Simon, the former Minister of Public Instruction, an influential member of the Academy of Moral Sciences. But a third candidate, M. Laugel, the scientific reviewer of the *Temps*, and the private secretary of the Duc d'Aumale, having been proposed by his patron and voted by him throughout the four scrutinies, no result could be obtained, the nominations being only made on an absolute majority. M. Laugel has written a few philosophical essays on scientific matters, and is a man of knowledge, but is not known except to a limited circle of friends.

IT is said that thirty young Chinese belonging to influential families are expected very shortly in Paris, where they are to be educated. They are under the care of a French naval officer, who, having joined the Chinese navy, has been appointed Director of Fow-chow Arsenal.

M. LEVERRIER has presented to the Academy of Sciences the observations on the transits of small planets made during the last three months at Greenwich and at Paris: the two Observatories are working conjointly in this department. Observations, limited to those asteroids which are near their apposition, have been made on twenty-two small planets; but the weather was so bad at both Observatories that only sixty-nine observations are recorded, sixty at Paris and nine at Greenwich. Generally the proportion is greater in favour of English observers, but the clouds were dreadfully against them during the last quarter.

We are informed that Mr. Chadwick, M.P., brought with him from California, on his recent visit, a box of superior Californian silkworm eggs. We understand that he is anxious to distribute them to anyone having a supply of mulberry-leaves and wishing to cultivate them. The eggs have been entrusted to Mr. Loose, the secretary of the Chamber of Commerce, Macclesfield, from whom small quantities can be obtained on application. Mr. Loose has also prepared a few simple instructions for feeding and keeping the cocoons.

The number of candidates at the recent General Examination for Women at the University of London was thirty-five. Of these, twenty have passed, viz., seven in honours, twelve in the first, and one in the second division.

Prof. J. Sachs, of Würzburg, is engaged in the preparation of a History of Botany, which is expected to be ready for publication in the course of the present year.

In answer to a request made by the Paris *Figaro*, M. Dumas has given the following details of the alleged effective remedy against Phylloxera :—All remedies discovered up to the year 1874 had the disadvantage that while destroying the obnoxious insects they did considerable harm to the vine itself; the experiments lately made with sulpho-carbonate of potash were, however, perfectly successful, as they do not effect the vine in the least; they were made by M. Milne-Edwards, Du Chartre, Blanchard, Pasteur, Thénard, and Boulay, in different wine-growing districts, particularly in the environs of Avignon, Cognac, Montpellier, and Geneva. The sulpho-carbonates are strewed on the ground, the next rain helps them to penetrate the soil, and the Phylloxera are completely destroyed by them. These salts at present are still rather expensive, but in the districts where the Phylloxera have only just appeared a very small quantity is sufficient, and it is hoped that if Government undertakes a larger production of the salts, the price will be considerably reduced.

The new Reptile House in the Jardin des Plantes, Paris, has sustained some heavy losses. A large turtle died from the shot it had received many months ago when captured in the Atlantic Ocean, and a large serpent from a wound inflicted by a rat. The rat having been offered as living food, resisted violently, and bit his adversary so deeply that he died a few days afterwards. The warders in the picturesque Reptile House will probably be more cautious in future in showing visitors the spectacle of Ophidians running after their food.

We are glad to say, however, that the above heavy loss will be to a considerable extent compensated, as the Jardin des Plantes will receive in a very few days a Boa more than eight yards in length, which has just arrived at Havre. We believe it takes a goat or a sheep to appease its appetite at one time.

A Geographical Society has been established in Roumania under the patronage of the present Prince. A great want has been felt of such an institution, not a single original work having been written by Roumanians on the geography of their native land. All geographical school-books are merely translations of foreign works, and are all full of errors, even as regards Roumania.

A correspondent of the *Pharmaceutical Journal*, Mr. G. C. Druce, suggests whether *Saxifraga tridactylites* is not a carnivorous plant. He states that the glands on the leaves present a very similar appearance to those of *Drosera*, and secrete a viscid fluid on being irritated. In a large number of plants which he examined he found the *débris* of some insect attached to the leaves.

The second of a series of industrial exhibitions projected by the Manchester Society for the Promotion of Scientific Industry was opened at Cheetham Hill, Manchester, on Friday last. The present show has been arranged for the special encouragement of appliances for the economy of labour.

A large deposit of amber has been discovered in the Kurische Haff, near the village of Schwarzort, about twelve miles south of Memel. It had been known for many years that amber existed in the soil of the Kurische Haff, from the fact that the dredgers employed by Government for the purpose of clearing away the shallow spots near Schwarzort that impeded navigation had brought up pieces of amber, which, however, were appropriated by the labourers; and no particular attention was paid to the matter till recently. Some speculative persons, reports our Consul at Memel, made an offer to the German Government, not only to do the dredging required at their own expense, but also to pay a daily rent, provided the amber they might find should become their own property. The proposal was accepted, and the rent fixed at twenty-five thalers for each working day. The dredging was commenced by four machines, worked by horses, which have increased in number and efficiency till eighteen other dredges and two tug-boats, with about 100 lighters or barges, employing altogether 1,000 labourers, are now engaged in the industry. The ground covers an area of about six miles in length, and a yearly rent of 72,200 thalers is paid by the company to the Government.

A new species of a new genus of serpents, collected by Lieut. Wheeler's expedition in Arizona during the field season of 1874, has just been identified and named by Prof. E. D. Cope. It is called *Monopoma rufipunctatum*. The rostral shield of this new genus resembles that of *Phimothyra*, and the lateral head shields those of *Cyclophis æstirus*. It is, however, more like *Eutænia* in general character. This is a very interesting discovery.

For some time past the United States steamer *Fortune*, commanded by Commander F. M. Green, has been engaged in the Gulf of Mexico and the West Indies, under the direction of the Hydrographic Office, in determining the latitude and longitude of certain points connected by submarine telegraph. Those so far decided are Panama, Aspinwall, Kingston, Santiago de Cuba, and Havana, in each of which places a portable observatory and astronomical instruments were set up, and numerous observations made. The longitudes were determined by the exchange of telegraphic signals, and the latitudes by the zenith telescope observations. During the course of this work numerous soundings were taken, and a very extensive series of specimens of the sea-bottom brought up. These have been submitted to Prof. Hamilton L. Smith, of Hobart College, Geneva, New York, who finds among them many new species, and others previously considered as very rare, and scarcely met with since their description by Prof. Bailey and others.

The Manchester Field Naturalists' Society issues a very modest Report for 1874, from which it seems that the Society is doing quiet, steady, satisfactory work; "the working members of the Society have steadily extended their knowledge, and latent taste for Natural History has been fostered and developed." This Society is a field club, and during 1874 had twelve successful excursions, interesting reports of which are given by Mr. F. J. Faraday.

Another Manchester society, and one that really deserves honourable mention, is that known as the Manchester Scientific Students' Association. From its Annual Report for 1874 it is evident that the Society does much good work in which a comparatively large proportion of the members take part. Their frequent excursions are not mere pleasure-trips, as, besides a leader, a lecturer is appointed, who generally takes up a parti-

cular subject and illustrates it from the observations and gatherings of the day. During the winter meetings are held for the reading of papers, many of which seem of considerable value. This Society was formed for the practical study of science, and on the whole this object appears to be well kept in view.

THE Cambridge Board of Natural Science Studies announce that applications by members of the University desirous of availing themselves of the facilities for study at the Zoological Station at Naples during the ensuing season, are to be sent to Mr. Foster, Trinity College, on or before the 20th of October.

AN appeal is made on behalf of the widow of the late Dr. Beke: that lady, it seems, having been left in very straitened circumstances. It is proposed to utilise the Beke Testimonial Fund for this purpose, and additional subscriptions are requested to be paid to Messrs. Cox, Biddulph, and Co., Charing Cross, or to Messrs. Robarts, Lubbock, and Co., Lombard Street.

WE would draw the special attention of our readers to an excellent new quarto work, abundantly and beautifully illustrated, on "The Marine Mammals of the North-western Coast of North America, together with an account of the American Whale-Fishery," by Capt. Charles M. Scammon. It is published at San Francisco by J. H. Carmany and Co. The figures of the characteristic attitudes of the different species of seals, as well as of the whales, in their native element and otherwise, are far superior to any we have ever seen, having all been evidently taken from the life. The volume is dedicated to the memory of Louis Agassiz.

PROF. SHALER has published a memoir upon the "Antiquity of the Caverns and Cavern Life of the Ohio Valley," in which he endeavours to show the period at which the animal life, so characteristic of Western caverns, received its first expression. He sums up his researches in the following propositions:—1. The extensive development of caverns in the Ohio Valley is probably a comparatively recent phenomenon, not dating further back than the latest Tertiary period. 2. It is doubtful whether there has been any extensive development of cavern life in this region before these caverns of the subcarboniferous limestone began to be excavated. 3. The general character of this cavern life points to the conclusion that it has been derived from the present fauna. 4. The glacial period, though it did not extend the ice-sheet over this cavern region, must have so profoundly affected the climatal conditions that the external life could not have held its place here in the shape we now find it, but must have been replaced by some Arctic assemblage of species. Under the circumstances, it is reasonable to suppose that most, if not all, the species found in these caves have been introduced since the glacial period. 5. We are also warranted by the facts in supposing that there is a continued infusion of "new blood" from the outer species taking place, some of the forms showing the stages of a continual transition from the outer to the inner form.

THE additions to the Zoological Society's Gardens during the past week include a Campbell's Monkey (*Cercopithecus campbelli*) from West Africa, presented by Capt. Damm; a Lesser White-nosed Monkey (*Cercopithecus petaurista*) from West Africa, presented by Mr. John Gordon; a Sloth Bear (*Melursus labiatus*) from Ceylon, presented by Mr. W. D. Wright; two Antarctic Skuas (*Lestris antarctica*) from the Kerguelen Islands, presented by the Rev. A. Eaton; a Proteus (*Proteus anguinus*) from the Adelsberg Caves, presented by Capt. R. F. Burton; a Persian Gazelle (*Gazella subgutturosa*), two Coatis (*Nasua nasica*), born in the Gardens; two Wapiti Deer (*Cervus canadensis*) from North America, an Ocelot (*Felis pardalis*) from South America, a Hoffmann's Sloth (*Cholopus hoffmanni*) from Panama, deposited.

ARCTIC MARINE VEGETATION

NOW that another expedition is about to sail for the Arctic regions through Davis's Straits, it is thought that some notice of the magnificent flora of the shores of Greenland may prove interesting. An essay on this subject,* written in Swedish, by Professor Agardh, the celebrated Swedish algologist, is now before me, but as it is too long for insertion in these pages, I will endeavour to condense as much of it as possible into an abstract.

During the Swedish Expedition to Greenland in 1870, a collection of Algæ was made on the Greenland coast, between Disco Island and Sukkertoppen, some degrees to the southward. These Algæ were afterwards examined by Professor Agardh, and in the essay above mentioned he gives us the result of his examinations, and some exceedingly interesting observations upon the characteristics of the marine flora of this Arctic district. It is not only the more or less numerous species which give to the marine vegetation in different zones a different character, but it is the abundance or scarceness of Algæ, their divarication in a greater or less degree from the common form and aspect, their great size, the multitude of individuals, and so on, which give every variable appearance to the seaweed-grown shores of different seas.

As in the northern region of the pine-tree, there are but few species, while the masses of forest are formed of an immense number of individuals which grow near together; so with regard to the northern marine flora, the principal portion of which is found to possess a general character, consisting of a few similar species, but, as before mentioned, of an immense number of individuals. Nearest to high-water mark are the species of Fuci; below them are the Laminariæ (Tangles, or seaweeds); these crowd on every rock and stone, and to each of them is attached its peculiar parasitic species. Occasionally, other species, belonging to the northern marine flora, stray into calm bays, inclosed caverns, or are carried away by strong currents. Compared with the weed-covered shores of Southern Europe, the uniformity of aspect on these Arctic shores is very great, and the number of species occurring there fewer than those of our own coasts. The principal characteristic of the vegetation of the colder seas is the gigantic size of the species of which it is composed, and this is especially the case with regard to the northern Algæ. *Laminaria saccharina* and *L. digitata*, *Himanthalia*, *Alaria*, *Scytosiphon filum*, &c., on our own coast, give but a feeble indication of what the more Arctic regions in this respect exhibit. When it is known that the Mediterranean and warmer seas contain some few species which from their great size are never found in Herbaria, one can understand how difficult it must be to find specimens suitable for Herbaria among the Arctic species. Professor Agardh lays great stress upon the importance of collecting specimens of these plants in all stages of their growth, and points out the great similarity to each other of young plants of different species, which makes it extremely difficult to discriminate the different species in the young state. The numerous examples, of all ages, brought home by the Swedish expedition, and especially those laid down in salt, could thus be examined in a fresh state, and enough of them might be dissected for the more accurate determination of these large-growing species. As Professor Agardh has referred here to salting down the Algæ, it may be as well to mention that in another publication he has stated that the best way of preserving Algæ is by the following process. In a cask or other convenient vessel put a layer of salt, then a layer of Algæ; then another layer of salt, then another of Algæ, and so on until the cask is full. Algæ thus preserved are found to be almost as fresh as when first taken out of the sea.

If in the extreme north the phanerogamous flora is characterised by dwarf forms, so do forms of an opposite character prevail in the marine vegetation of the Arctic regions. To a certain degree the aspect of the magnificent Arctic marine vegetation depends upon the common large-growing Laminariæ, which constitute a considerable and characteristic portion of it. Laminariæ are also found in the Southern Ocean, and there are even other large Algæ, as, for example, the species of Iridæa, in the North Pacific, which have much larger dimensions in colder oceans than have analogous species in the warmer seas. So, also, the great number of species of Laminaria in the Arctic seas is an indication

* Bidrag till kännedomen af Grönlands Laminaricer och Fucaceer af J. G. Agardh, inlemnadt till K. Vet. Akad. den 27 Sep. 1871. (Stockholm, 1872, P. A. Norstedt and Söner.)

that if these prevail the number of other species is relatively less. While, on the other hand, only one species of Laminaria with an entire, and one with a laciniated frond, is found on the Swedish coast, there are on the coasts of Spitzbergen and Greenland at least five species of Laminaria. The *L. cuneifolia* of Greenland is about the same size as *L. saccharina;* but *L. longicruris*, one of the commonest Algæ of Greenland, is very large; the stalk, which is sometimes many ells * long, bears a lamina (frond) of equal size. Some specimens had been seen by Prof. Agardh, which, including both stem and frond, were eighty feet long. Ruprecht mentions an Alaria from the Sea of Okhotsk, the frond of which was about the same breadth as that of the common European form, which had a length of more than fifty feet. From Spitzbergen comes another species of this genus, whose frond is as much as one ell in length and about three ells long; and also another species several ells long, with a stem as thick as a finger. But it is especially in the north part of the Pacific, on the North American coast, that the richness of the Laminarian forms and their great size are most conspicuous. The species of Alaria, Arthrothamnus, Thalassiophyllum, Agarum, and Nereocystis together constitute such a magnificent marine flora, that one feels a difficulty in forming an idea of the smaller representatives of the same group which are found in other seas. *Nereocystis Lutkeana* has a stalk 270 feet in length, when it swells into a bladder that bears a tuft of fronds which are quite twenty-seven feet in length. In the Antarctic seas the analogues are to be found, the Durvillæa, and Lessonia of Cape Horn, Ecklonia of the South African coast, the species of Macrocystis, &c., are well-known examples of the large Algæ which are found there.

It is perhaps less surprising that a rich marine flora should appear on the coast of Spitzbergen wherever a considerable branch of the water of the Gulf Stream follows the coast, and in proportion receives a higher temperature and a greater degree of saltness. But in Greenland it may be otherwise. Cold currents are said to flow along the west coast of Greenland upwards, as well as on the opposite coast of America downwards.† During a considerable portion of the year the sea appears to be frozen along the coast, and even during the summer months drift ice is reported to be continually seen in the open sea. Under such conditions, although a marine vegetation of large size appears there, it may be assumed that an ice-cold or nearly ice-cold sea by no means prevents a great development of Algæ, where the other conditions necessary for their growth are found. One is tempted to believe that the great abundance and size of the marine flora on the coasts of the colder seas, on the one hand, and on the other the richness of the open seas in Diatomaceæ, are in some measure the cause of the abundance of animal life which prevails in these regions, and which, in the regularity of its limits, may afford a hint to the expeditions for carrying on the whale fishery that every year employs thousands of vessels. "It has been remarked," says Ruprecht, "that the northern boundary of the large sea animals is found where the coast is most bare of Algæ;" and Maury ("Physical Geography of the Sea") remarks on the superior flavour of fish from the colder waters, and the greater excellence of the principal fishery grounds of the world, which are all situated in the colder waters.

In direct opposition to what occurs on the Greenland and Spitzbergen coast, Ruprecht states that the whole coast of Behring's Sea north of the Aleutian Islands is almost entirely without marine vegetation; an astonishing statement, as not only on the Aleutian Isles, but also on the American coast to the south of them, the marine flora is rich and is developed on a grand scale. Ruprecht's statement that the whole Arctic sea of Siberia, eastward from the Gulf of Kara to Behring's Sound, is almost entirely without marine vegetation, is almost open to doubt, since Prof. Agardh possesses specimens of two Algæ in good preservation which were taken near the mouth of the Lena, and Ruprecht himself mentions another Alga which was found in Behring's Sea. Should it be ascertained that while the rocks of the Arctic Sea, wherever they have been examined, namely, in Norway, Spitzbergen, Greenland, and the coasts of America, present, through the number of individuals and their great size, a peculiar marine vegetation, while, on the other hand, eastward from the Gulf of Kara the sea should be found to be very poor as regards its flora, or even desitute of these large Algæ, perhaps one might under these circumstances form an opinion that the Baltic Sea was one of the former gulfs of the Arctic Ocean, and at a later period was separated from it; hence great interest attaches to the study of the Algæ of the Baltic Sea. The character of extraordinary scarcity of Algæ, which according to Ruprecht characterises the Arctic Ocean, also prevails in the Baltic Sea, where long ranges of rocks, broken like those of the Atlantic into bays, and apparently well adapted to harbour a rich vegetation, are entirely bare of vegetation, while the rocks and rock-pools on the western coast are crowded with Algæ. The stunted representatives of marine Algæ that most generally appear in the southern and western parts of the Baltic Sea may perhaps have come at a later period from the west, after the Baltic was united with the Atlantic.

More accurate information relative to the Algæ and their alleged scarcity in the Siberian Sea and Behring's Sound are still wanting, but *à priori* one is scarcely entitled to assume that the Algæ in these localities should differ materially from the uniform character of gigantic size which seems to distinguish the vegetation of the other Arctic Sea. On the other hand, that the Baltic Sea, as well in respect of the number of individuals as of their development, is in direct opposition to the vegetation in the other northern sea, is undeniable. But the Baltic Sea is in a peculiar state. It is an enclosed sea, into which large fresh-water rivers discharge themselves, and a freezing sea, ice-covered during a considerable part of the year, in a great degree prevents evaporation. Both these circumstances may cause the Baltic to be considered almost as a fresh-water basin, into which salt water flows from the sea almost entirely through the Kattegat and more south-westerly parts, and in the deep water retains some perceptible degree of salt. The influence of the salts on the growth of Algæ is at present but little understood, but that they have great influence cannot be doubted. The Algæ which appear in the Baltic cannot be said to indicate a high northern or north-eastern origin. They seem to be the Algæ of the Kattegat in a dwarf form. Some few species of Algæ appear to be peculiar; but in this case they do not prove that the Baltic was once a gulf of the Arctic Sea.

It has been already remarked that a scarcity of forms and abundance of individuals is a characteristic of the marine vegetation of the northern ocean. Nevertheless it must not be concluded from the scarcity of forms which prevails in every separate locality, and of which a few species of each constitute the principal masses of marine vegetation, that the same species prevail everywhere. We should then fall into the error of the older botanists, who thought that they recognised in foreign Algæ many well-known forms of the European flora, which outwardly bear a great resemblance to each other. With regard to the northern Laminariæ and Fucaceæ, it may yet be shown that there are analogous—if not identical—species, which appear in different localities, and that the species resembling each other in aspect, also in their *habitat* resemble each other, and thus constitute representative species. The circumstance that at first one does not perceive the difference between species bearing similar names from different localities, is but weak evidence of the identity of the forms which under the same names were supposed to prove that all these so-named European species actually appeared on the coast of Australia; although we might justly allege this fact as a proof of changes which might have broken the former connection between the seas, and so prevented migration from taking place at the present time. So soon as accurate examination is made, important variations are observed to exist between many species which pass under similar names, and some doubt may be entertained, not only whether they constitute entirely different species, but even whether they do not sometimes belong to entirely different genera.

Such representative species appear in many, and in perhaps most genera; but in Laminaria and Fucus there are some analogous forms which are very similar to the eye; there being in each genus two principal forms only, while each possesses many species which bear a great resemblance to each other. The similarity is, in reality, here so great that many were for a long time considered, and many more may probably even henceforth be considered, as modifications of the same species.

The difficulty of characterising the species of Laminaria is really very great, not only on account of the great resemblance between them, but also because the species change their aspect

* A Swedish ell is equal to two feet.—M. P. M.

† In the narrative of the North German Expedition it is stated that on the east coast of Shannon Island, lat. 75° 29′ N., drift-wood, identified as alder (*Alnus incana*, L.) and poplar (*P. tremula*, L.) was washed ashore, thus plainly showing that the drift-wood of N.E. Greenland comes originally from N. Siberia; whence, driven into the sea by the strong currents, it floats in a westerly direction north of Spitzbergen, and is carried on until it reaches Greenland, where it takes a southerly course. See vol. ii. p. 537.—M.P.M.

during different periods of their development, and this more frequently in an analogous manner. During the first period they are so like each other that it is almost impossible to separate one from the other the younger forms of the most dissimilar species. They all begin with a short stalk and an undivided frond (lamina); then the stalk continues short in some, and lengthens considerably in others; in some the lamina continues undivided; in others it is cloven. But it is especially to be observed that this lamina, whether undivided or cloven, is variable in most species. Thus, all are at first small and extended in length, with a more or less wedge-like base; but the wedge-like base becomes heart-shaped and even kidney-shaped in some; in others it retains a wedge-like form throughout its whole state of development. Most species periodically change their lamina; with the change the new lamina becomes larger and broader than the old one. The young lamina is thin; in colour rather inclining to green than to light brown; in different species the lamina is at a later period thinner or thicker, and with a different tint of colour. The fructification appears in different species not only in different parts of the lamina, but the sori extend in different directions, although they do not seem to assume precise forms. The characteristics of species must therefore be judged, not from the peculiarities of appearance, but by the whole development of the plant, the differences of which are with difficulty comprehended, unless the species throughout their whole range of growth be accurately compared with each other. Considering that certain characteristics are scarcely perceptible except when the plants are in fresh condition, and that collectors are contented with preserving portions or incomplete specimens only, we cannot wonder that the species of Laminaria should be confounded with each other.

Greville had named a Laminaria from the coast of Africa, *L. pallida*, from a modification in its colour. Younger forms, in which the colour was less evident, or the lamina not yet cloven, were referred by many algologists sometimes to *L. digitata*, sometimes to *L. saccharina*. But between these northern species and that of the Cape, lies an ocean which it is difficult for a Laminaria to pass. Although the characters which separate *L. pallida* and *L digitata* are not more important than those which separate *L. digitata* from *L. stenophylla*, it must, nevertheless, be considered that *L. pallida* is a distinct species.

L. longicruris is the most common as well as the largest of the Greenland Laminariæ. It is the representative on their coast of *L. caperata*, a native of Spitzbergen, no specimens of which have been seen from Greenland, neither has *L. longicruris* yet been found at Spitzbergen. From Greenland *L. longicruris* spreads down the American coast as far at least as the forty-second parallel, and one specimen is reported from the Bahamas. Portions of this species have been cast ashore on the coasts of Norway, Ireland, and Scotland. In Gunner's "Flora Norvegica," a form is mentioned under the name of *Ulva maxima*, which Agardh considers to be *L. caperata*; the same form has also been found on the north coast of Scotland.

The Berggren collection also contained a great number of examples of Laminaria that, by Dickie (Algæ from Cumberland Sound, in Linn. Soc. Journ. vol. ix. p. 237) and by Croall (in Brown's "Flora Discoana," Trans. Bot. Soc. Edinb. p. 459), was called *L. saccharina*. Prof. Agardh considers the above-mentioned plant as identical with his *L. cuneifolia*. He states that he has never seen a specimen from Greenland of *L saccharina* as it appears on our coast. *L. cuneifolia* is an example of a species which is found near Greenland and also in the northern part of the Pacific. The Alga described by Ruprecht under the name of *L. saccharina v. lessoniæfolia* may be a smaller form of the same species. Specimens from Newfoundland and Scotland have been seen, which may belong to the same species. *

Of *L. solidungula* there are specimens from Ritterbank and Jakobshavn. This species seems to have a wide range in the Arctic sea, appearing at Spitzbergen, Greenland, and in the northern parts of the Pacific, if, under this species, is to be accepted some specimens with disciform roots described by Ruprecht.

In the same collection is a new species with laciniated frond, named *L. atro-fulva* from its dark colour, which distinguishes it from every other species, in all stages of its growth. Excepting *L nigripes*, it is the only Laminaria from Greenland with a laciniated frond. Neither Dickie nor Croall mentions it in their lists of Algæ. In a note to the Flora Discoana it is mentioned that in another collection *L. digitata* was found. From such a statement one may, nevertheless, be unable to determine which Laminaria with laciniated lamina was here referred to. That *L. digitata*, so common on the European and Spitzbergen coasts, should not be found in Greenland was so much the more singular, that it was thought to be common at Newfoundland, and is stated by Harvey to appear on the American coast as far south as Cape Cod. Postel and Ruprecht also mention it as existing in the North Pacific, but perhaps the specimens seen belong to other species. *L. Bongardiana*, with which *L. atro-fulva* most nearly agrees, is said to have a canaliculated stem, by which it is easily separated from the Greenland species.

Of *L. dermatodea* there is only one specimen in this collection. It is probably rare in Greenland. This species is found at Newfoundland, Spitzbergen, and Norway.

L. Fascia is included in the Berggren collection, but is not met with at Spitzbergen.*

A Greenland specimen, called *Scytosiphon filum*, was in a state of preservation too imperfect to be determined.

The most beautiful and characteristic species of the Greenland marine flora are, undoubtedly, those of Agarum, a genus which belongs also to the northern part of the Pacific. The Greenland species extend down the North American coast and that of Newfoundland, but not a fragment of this genus has as yet been found on the Spitzbergen and European coasts. It appears to be common in Greenland. The Greenland species vary in the breadth of the costa and the closeness of the holes with which the frond is pierced, but Agardh knows of no other difference, and refers all the specimens to one species, namely, *A. Turneri.*

Among the Laminariæ, included in the collection, few are of greater interest than the form of Alaria taken in Sukkertoppen in great abundance and of all ages. Hence Prof. Agardh has been able to characterise the different Greenland species of Alaria, which are as follow:—*A. esculenta*, *A. musæfolia*, *A. Pylaii*, *A. membranacea*, and *A. grandifolia.*

Next to the Laminariæ the Fucaceæ form the most considerable part of the Berggren collection. They consist chiefly of the more Arctic forms brought home from Spitzbergen, with some differences. Of the forms common on the north coast of Europe (*Fucodium canaliculatum*, *Fucus serratus*, *Halidrys siliquosa*) which have not been found on the coast of Newfoundland or America, there are not any examples in the Greenland collection. Of these, *F. serratus* only is found at Spitzbergen, but this differs from the true European form. With *F. serratus* may be compared *F. edentatus* of Newfoundland. *F. canaliculatum* was compared by Harvey with *F. fastigiatum* of California. Analogous species probably represent each other in different localities. Of *Fucodium nodosum*, some examples, taken from different localities, are found in the Greenland collection.

Fucus vesiculosus, so common along the European coast even up to the extreme north of Norway, is absent, or at least very scarce, at Spitzbergen, but is one of the commonest of the Greenland species. It is found there both with and without vesicles. Besides *F. vesiculosus*, the collection contains numerous examples of *F. evanescens*, J. Ag., *F. Miclonensis*, and *F. filiformis*, which grow together, and in the same locality as *F. vesiculosus*, which is distinguished from the others by its stout consistence and by its drier surface, while the others give out more mucus. It is also easy to separate extreme forms of *F. evanescens*, *F. Miclonensis*, and *F. filiformis*, but among the abundance of specimens brought from Greenland intermediate forms appear, so that it is often difficult to decide the boundary between these species. When extreme forms lie together, *F. filiformis*, so different in its aspect from *F. evanescens*, is without doubt much more nearly related to *F. evanescens* than to *F. distichus*, with which it has long been confounded and considered identical.

Among the Greenland collection is one which differs from any that Prof. Agardh had seen, but which agrees most nearly with *F. filiformis*, although it is separated by fixed characters from all the species previously received. The smallest forms come nearest to *F. balticus*, like that forming globular vesicles which probably float the plant with ease into deeper water. It has been named *F. divergens.*

The fact that the species of Fucus, more than those of various

* Near Walrus Island, lat. 74° N., great quantities of marine plants, chiefly consisting of a large Laminaria, were washed up by the ice and the tide, or were lying in hollows. See Narrative of North German Expedition, vol. ii. p. 518.—M. P. M.

*In the narrative of the German Arctic Expedition (vol. ii, p. 345) *L. Phyllitis* is stated to have been found all along the East Greenland coast among and under the ice. This is the first time I believe that this Alga has been reported from so high a latitude. It was accompanied by *Desmarestia aculeata*.—M. P. M.

other genera, appear to be formed upon a single type, contributes naturally to the common opinion that the genus has few but much-varying species. In describing the Greenland fo:ms, Prof. Agardh has endeavoured to show that besides the difference in form, deviations also occur which ought to be retained as characteristics. In a preceding memoir he had stated that the differences noticed by other algologists in the antheridia and spores being formed in the same or in separate receptacles may possibly be explained thus: namely, that in different seasons the receptacles differ in this respect. Should such an explanation prove to be erroneous, it will undoubtedly be seen that it is these differences, more than others, that deserve to be considered as the characteristics of species.

The reader who wishes for further information relative to the species of Algæ inhabiting the Arctic seas is referred to the list of Arctic Algæ in Harvey's Ner. Bor. Americana, and to Dr. Dickie's List of Algæ obtained in Cumberland Sound (Journal of Linn. Soc. vol. ix.) Perhaps also some of the Algæ collected by Dr. Lyall on the north-west coast of America, thirty-two of which had not been found elsewhere, may extend to the Arctic Sea. See Harvey's List of Algæ, collected by Dr. Lyall, Journ. of Linn. Soc. vol. vi.

MARY P. MERRIFIELD.

SCIENTIFIC SERIALS

American Journal of Science and Arts, April.—The principal contents of this number are: The history of Young's discovery of his theory of colours, by Alfred M. Mayer. The aim of this paper is to give extracts from Newton, Young, and Wollaston, which embody the early literature of Young's celebrated theory of colour, and to furnish a history of the steps by which he was led to the adoption of what is now known as Young's theory of colour-sensation.—A re-determination of the constants of the law connecting the pitch of a sound with the duration of its residual sensation, by Alfred M. Mayer. This article refers to a previous article of October 1874 on the same subject. Since then, Madame Seiler (who assisted Helmholtz) and Dr. Carl Seiler have spent considerable time in re-determining the durations of the residual sonorous sensations, using Mr. Mayer's apparatus. From their experiments he has found the law given before as $D = \left(\frac{53248}{N + 23} + 24\right)\cdot 0001$ requires to be modified to $D = \frac{3\cdot 2}{N + 31} + \cdot 0022$, where $D =$ the durations of the residual sonorous sensation corresponding to N number of vibrations per second.—On the action of the less refrangible rays of light on silver, iodide, and bromide, by Carey Lea. The result of 160 very concordant experiments shows that AgBr and AgI are sensitive to all the visible rays of the spectrum. AgI is more sensitive than AgBr to all the less refrangible rays and also to white light. The sensitiveness of AgBr to the green rays was materially increased by the presence of free silver nitrate. AgBr and AgI together are more sensitive to both the green and the red rays than either AgI or AgBr separately.—On the Silurian age of the Southern Appalachians, by F. H. Bradley. First portion (to be continued).—Spectroscopic examination of gases from meteoric iron, by Arthur W. Wright. On the supposition that meteoric iron has received its hydrogen and other gases from the sun or some other body having a similar atmosphere of great density, it seemed probable that a spectroscopic examination might reveal the unknown gaseous elements assumed to be present in the solar corona. Only negative results were obtained. But the fact incidentally observed of the varying character of the oxygen and hydrogen lines in the presence of hydrogen, and the near coincidence of two of them with prominent coronal lines, with the possible coincidence of a third line, goes to show that the characteristic lines in the spectrum of the corona, so far from indicating the presence of otherwise unknown elements, are simply due to hydrogen and the gases of the air, oxygen and nitrogen.—On the duplicity of the principal star of Σ 1097, by S. W. Burnham.—The original notes under the head of Scientific Intelligence are: Progress of Geological Survey of Canada, 1873–74; the genera Opisthoptera (Meek, 1872) and Anomalodonta (Miller, 1874); the Gulf of Mexico in the Miocene time.

Der Naturforscher, Nos. 1 to 5, 1875.—This part contains many papers reprinted from other journals, besides several original contributions. We note the following:—On the physiological action of amyl nitrite and the causes of blushing; investigations made by Herr Wilhelm Filehne, who found that amyl nitrite acts upon that part of the brain which is also acted upon when the individual has the feeling of shame and blushes. The most interesting part of the paper is the description of the effects of amyl nitrite upon animals; accelerated breathing and palpitations were the result, evidently similar to the physiological phenomenon in man. In the latter case, whether produced by the ether or by psychic emotion, the phenomenon is exactly the same.—Report on the Crustacea observed on board the *Challenger* between the Cape of Good Hope and Australia, in the Antarctic seas, by Willemoes-Suhm.—On the ascending currents of air in our atmosphere, by J. Hann.—On the finer structure of the electric organs of fish, especially of the species Torpedo, Malapterurus, and Gymnotus, by F. Bol.—On the point of combustion: a lecture delivered by A. Mitscherlich before the Chemical Section of the Association of Naturalists at Breslau.—On the fossil Cetacea of Europe, by J. F. Brandt.—On the diatoms of the coal age, by F. Castracane. The author succeeded in proving the existence of diatoms in a piece of Lancashire coal; it was powdered finely, and burnt in a stream of oxygen. The residue was treated with nitric acid and chlorate of potash, and then washed. The species he found were all sweet-water species, with the exception of a Grammatophora, a little Coscinodiscus, and an Amphipleura, and comprised the following:—*Fragilaria Harrisonii*, Sm.; *Epithemia gibba*, Ehrbg.; *Sphenella glacialis*, Kz.; *Gomphonema capitatum*, Ehrbg.; *Nitzschia curvula*, Kz.; *Cymbella scotica*, Sm.; *Synedra vitrea*, Kz.; and *Diatoma vulgare*, Bory.—On the Chætopoda of the Atlantic, by E. Ehlers; account of the results of a collection made on board the *Porcupine* in 1869.—Studies on the diameter of the sun, by P. Rosa. These studies were published after the death of the author, by Fathers Secchi and Ferrari, and contain many interesting details which are well worth the attention of astronomers.—On the absorption spectra of some yellow vegetable colouring matters, by N. Pringsheim. The result of these investigations seems to be that these colouring matters are merely modifications of chlorophyll, and that there exist numerous modifications of this substance, from the brightest yellow to the darkest green.—On the influence of the concentration of blood upon the motion of the blood-corpuscles.

SOCIETIES AND ACADEMIES

LONDON

Physical Society, May 8.—Prof. Gladstone, F.R.S., president, in the chair.—Mr. Crookes, F.R.S., exhibited and described some very important experiments on attraction and repulsion resulting from radiation, which he has recently submitted to the Royal Society, and of which an account has already been given in this journal (vol. xi. p. 494). It is unnecessary therefore to describe them at length, but it may be pointed out that the most beautiful of the instruments is one which Mr. Crookes calls a radiometer. It consists of four arms suspended on a steel point resting in a cup so that they are capable of revolving horizontally. To the extremity of each arm is fastened a thin disc of pith, lampblacked on one side, the black and white faces alternating. The whole is enclosed in a glass globe, which is then exhausted as perfectly as possible and hermetically sealed. Several of these instruments varying in delicacy were exhibited, and experiments made showing the influence of light and heat of different degrees of refrangibility, and in proof of the law of inverse squares, &c.—The President, in expressing the cordial thanks of the Society, referred to Mr. Crookes' statement that the repulsion was proportional to the length of the vibrations, and asked whether at the red end of the spectrum there was an abrupt termination of the action, and a gradual diminution towards the ultra violet.—Mr. Walenn inquired as to the action of the magnet and of different axes of crystals in causing repulsion.—Prof. Woodward made some observations with reference to the manipulation.—Prof. Guthrie paid a graceful compliment to Mr. Crookes' work, and observed that researches might be divided into two classes; those in which the value of the work outweighed the merit of the author, and those in which a result of comparatively trifling significance is the outcome of years of patient labour. He expressed a strong conviction that Mr. Crookes' research had, in an almost unparalleled degree, both elements of greatness.—Mr. Crookes stated, in reply to Dr. Gladstone's question, that the glass envelope of the radiometer

must be taken into account in considering the action of the rays of different refrangibility, and further, that the increased effect due to red light may have been in part due to the concentration of rays of low refrangibility which attends the use of glass prisms. A diffraction spectrum might give a different result. He added that when a ray falls on a surface capable of motion, which reflects it, very little work is done, but if the surface quenches the ray, motion is produced. He then thanked Prof. Guthrie for his kindly remarks.—Prof. Cornu, of the École Polytechnique, described his recent experiments on the determination of the velocity of light. He gave an account of the method of Foucault, and exhibited the complete apparatus, including the arrangement of mirrors for multiplying the distance traversed between the two reflections from the revolving mirror (NATURE, vol. xi. p. 274).—Prof. Adams, vice-president, mentioned that M. Cornu had contributed in no small measure to the success which had attended the formation in France of a society closely corresponding to our British Association, and assured him that the Physical Society felt grateful for his presence, as he could well understand the difficulties with which the early days of such a society are beset.—M. Cornu stated, in answer to a question of Prof. G. C. Foster, that he objected to the revolving mirror method, because the distance to be traversed by the light was very small, and because the path of the ray lay through a vortex of air produced by the rapid revolution of the mirror.

Royal Horticultural Society, April 7.—Scientific Committee. A. Grote, F.L.S., in the chair.—A communication was read from W. Wilson Saunders, F.R.S., describing a diseased condition of young poplars planted on the sides of roads in East Worthing. The disease seems sooner or later to be fatal to the tree, for he had not seen one tree attacked of which there seems any chance of recovery. The trees are from twelve to eighteen feet high, and with stems varying from five to seven inches in diameter. The disease is most apparent in large, rough, open wounds about the commencement of the lower branches, and on the stem; but upon closer examination symptoms of the disease will be found all over the tree, even to the tops of the branches. The disease seems to show itself at first by a longitudinal fissure in the bark, which fissure is nearly straight and but of little depth, having its lips slightly elevated and reflexed. At first the fissure does not penetrate the whole depth of the bark, but, gradually deepening and extending in length, the wood becomes exposed. This continues until the wood is quite exposed, and in a branch of two years' growth the disease assumes the appearance of a long open wound, exposing much of the wood which the growth of the bark partially covers up. Tracing the progress of the disease further, side fissures will be seen producing the same results; and these fissures, running one into the other, break up the bark until occasionally the disease extends all round the branch. When a branch gets diseased, the portion above the wound dies. The disease is often slow in progress, particularly when on the main stem, large open wounds then appear, of the same character as those on the branches, exposing much of the wood, but having the surrounding bark, although diseased and cracked, in a healthier state.—Mr. M'Lachlan referred to a note in the report of Lieut. Carpenter, of the American Geological Survey, in which it was stated that the Colorado Potato Beetle was distributed by means of seed potatoes, and that its absence in Utah and other parts of California was to be attributed to the fact that it has not yet been necessary to import seed potatoes.—Mr. Hemsley sent a turnip with a cavity in the interior of the root nearly filled by leaves growing from the crown downwards and inwards.—Prof. Thiselton Dyer exhibited under the microscope a portion of the plasmodium of *Æthalium*, showing the "streaming" movements of the protoplasm of which it is composed.

General Meeting.—W. Burnley Hume in the chair.—The Rev. M. J. Berkeley commented on the objects exhibited, including a group of species of *Drosera* and *Drosophyllum* exhibited by Messrs. Veitch.

April 21.—Scientific Committee.—Andrew Murray, F.L.S., in the chair.—The Chairman remarked that from his own observation there could be no doubt that the Colorado Potato Beetle was perfectly able to live in the climate of Canada.—Mr. Edmonds sent from the Gardens at Chiswick House a basket of *Peziza lanuginosa*.—Dr. Masters exhibited shoots of peach-trees which had been killed owing to having been thickly painted with colza oil.—Mr. Wilson Saunders communicated a note on a monstrous condition of the early St. John's Cabbage. When the bed of cabbages was about at its best, a long, warm, very dry period was succeeded by much rain. The sudden impulse given to vegetation by this soon caused the solid heads of the cabbage to burst, and in a few days a series of smaller, well-shaped, rounded, compact heads were formed from the central axis of growth, closely touching each other, and backed up by the leaves of the original head, which remained green and full of sap. The number of these smaller heads varied from three to six in each cabbage.—Prof. Thiselton Dyer read an abstract from the *Sitzungsbericht der Gesellschaft Naturforschender Freunde zu Berlin* for Nov. 17, 1874, in which an account was given by Magnus of the production of graft hybrids in the potato by Reuter, the chief gardener at Potsdam, in 1874. He used the white long Mexican and the dark grey black kidney, both of which sorts had been introduced from America by the Novara Expedition. A wedge-shaped piece of the former, bearing an eye, was grafted upon the latter. The graft hybrids exhibited an intermediate character in form between the parents. They were broader and thicker than the long thin Mexican, longer than the black kidney. One of the potatoes also exhibited a blending of the colours. The two ends were red, and the middle zone a greyish yellow. The dark grey colour of the black kidney is produced by the intense red sap in a layer of cells covered by the corky rind. In a subsequent communication Magnus mentioned similar experiments which had been made by Dr. Max Heimann, and communicated to the botanical section of the *Schlesischen Gesellschaft* in the *Sitzungsbericht* for Nov. 19, 1872. Magnus described similar results obtained by Dr. Neubert, of Stuttgart, by herbaceous grafts of the stems.

General Meeting.—W. Burnley Hume in the chair.—Prof. Thiselton Dyer commented on the objects exhibited.

Anthropological Institute, May 11.—Col. A. Lane-Fox, president, in the chair.—Mr. Moncure D. Conway, M.A., read a paper on Mythology. He maintained that the evolution of mythology was the reverse of what the facts of physical evolution might suggest; it was not from beneath upwards to higher things, but rather from the grand in nature that the human mind had arrived at the association of mystical meanings with the stock and stone, plants and animals, which figured so largely in popular mythology. Sacred animals were consecrated as symbols of the higher phenomena. Flowers and plants derived their potency from connection with solar or lunar influences, still represented in the belief that to be healing they must be gathered at certain holy times or at certain phases of the moon. It was also maintained that the gods were personifications of power, and unmoral; they were gradually divided into good and evil, the demoniac powers being for a long time not diabolical, but personifications of hunger, thirst, and the dangers and impediments of life. The idea was combated that men had ever worshipped purely evil powers. The legend of Eden was held by Mr. Conway to be inexplicable by Semitic analogues. In India were found the myths of serpent-guarded trees and the apple of immortality, and the curse on the serpent which had puzzled theologians was explained by the theory of transmigration.—A paper by Rev. A. H. Sayce, M.A., was read, on Language and Race. The author held that the fallacy of language as a sure and certain test of race is one to which few modern philologists would commit themselves. There was no assertion which could be more readily confronted with history, or, when so confronted, more clearly be demonstrated to be false. Society implied language, race did not; hence, while it might be asserted that language is the test of social contact, it might be asserted with equal precision that it is not a test of race. Language could tell us nothing of race. It did not even raise a presumption that the speakers of the same language were all of the same origin. It was only necessary to look at the great States of Europe, with their mingled races and common dialects, to discover that language showed only that they had all come under the same social influences. Race in philology and race in physiology meant very different things.—Mr. A. W. Franks, F.R.S., exhibited an inscribed wooden gorget from Easter Island.

Entomological Society, May 3.—Sir Sidney Smith Saunders C.M.G., president, in the chair.—The President exhibited male specimens of *Stylops*, taken by himself in the pupa state, on *Andrena atriceps*, at Hampstead Heath, on the 6th, 9th, and 17th April last. Mr. Enoch, who had been there on the 6th at an earlier hour (between nine and ten o'clock) had been still more successful, having captured 17 males, one of which, however, was taken after 2 P.M. The President drew attention to the remarkable difference observable in the cephalothorax of the

females in these specimens, as compared with those met with on *Andrena convexiuscula*, and remarked on the importance of not confounding the species obtained from different *Andrenæ*, *Stylops Spencii* having been described from *A. atriceps*, while *S. Thwaitesii* had been described from *A. convexiuscula*. Mr. Smith believed that eventually a great many species would be found to inhabit this country, and that as many as a dozen different species would probably be found on the genus *Andrena* alone, independently of *Halictus*.—Mr. M'Lachlan read an extract from a report made to the Royal Society, on the Natural History of Kerguelen's Island, by the Rev. A. E. Eaton, who was attached as Naturalist to the Transit of Venus Expedition to the island (NATURE, vol. xii. p. 35). Nearly all the insects were remarkable for being either apterous or with greatly abbreviated wings. Mr. M'Lachlan said that the theory as to the apterous condition of the insects was that the general high winds prevailing in those regions rendered the development of wings useless; and Mr. Jenner Weir remarked that the apterous condition was correlated with the fact that plants under similar circumstances were apetalous and self-fertilising; and hence it was supposed that the existence of winged insects was unnecessary.—Mr. C. O. Waterhouse exhibited a *Chelifer* which he had discovered under the elytra of a *Fassalus* from Rio Janeiro.—Mr. C. O. Waterhouse also exhibited a drawing of a Neuropterous insect of the family *Ascalaphidæ*, from Swan River, presenting the peculiarity of having a large bifid hump on the basal segment of the abdomen, dorsally, each division of the hump bearing a crest of hairs. He believed it to be the male of *Suphalasca magna*, M'Lachlan.—Mr. Wormald exhibited a collection of Coleoptera, Neuroptera, and Lepidoptera, sent by Mr. H. Pryer, from Yokohama.—Prof. Westwood communicated descriptions of some new species of short-tongued bees belonging to the genus *Nomia*, Latreille; and also a paper, on the species of *Rutelidæ* inhabiting Eastern Asia and the islands of the Eastern Archipelago.—Mr. C. O. Waterhouse communicated a description of a new species belonging to the *Lucanidæ* (*Prosopocœlus Wimberleyi*), by Major F. J. Sidney Parry; and also a description of the male of *Alcimus dilatatus*, by himself.

Royal Microscopical Society, May 5.—Mr. H. C. Sorby, F.R.S., president, in the chair.—A discussion took place upon a paper read at the last meeting by the president, upon spectrum analysis by means of the microscope, and some additional particulars of interest were furnished by the author in reply to questions addressed to him by Dr. Pigott, Dr. Matthews, Mr. Slack, and Mr. Crisp.—Mr. Slack read a paper on the relation of angular aperture to surface markings and accurate vision, in which he showed the fallacy of the present system of using high-angled objectives for these purposes to the exclusion of those of small angular aperture, and pointed out that extreme angles were only to be obtained at the expense of accurate correction and penetrating power.

CAMBRIDGE

Philosophical Society, May 3.—A communication was made by Mr. Pirie, on a method of introducing a current into a galvanometer circuit. Mr. Pirie said that electricians had often to work with currents far too strong for their galvanometer. He mentioned various methods in use for checking the swing of the needle; but contended that an easily made and easily used controller for rough work was a desideratum. He described an instrument in the form of a continuously varying shunt, in which a moving connection was obtained by a tube filled with mercury sliding on a wire of suitable resistance. This form of connection was first used by Prof. Barrett of Dublin. With the aid of Mr. Garnett, the Demonstrator of Physics, Mr. Pirie showed that a very good connection was obtained by this means; and subsequently, that the instrument described gave a control over the movements of the needle in a galvanometer whose resistance was not too different from its own.

GLASGOW

Geological Society, April 15.—Mr. James Thomson, F.G.S., vice-president, read a paper on the geology of the River Liddel, Dumfriesshire. He described several fine sections exposed along the banks of that river, showing wonderful contortions, with great "faults" and "down-throws" of strata. He also referred to the striking identity of the fossils found in a band of impure limestone in that district with those found in many parts of the Ayrshire and Lancashire coal-fields.—Mr. Thomson also read some notes on new species of carboniferous corals, giving an account of his recent investigations in that department.

BERLIN

German Chemical Society, May 10.—T. Böhm studied the influence of various salts on the growth of *Phaseolus multiflorus*, and found lime salts alone efficient for the culture of these plants.—G. Gerlich, bringing into contact sulphocyanide of potassium or of ammonium with bromide of allyl, obtained sulphocyanide of allyl when the reaction was allowed to take place at 0°, while at higher temperatures the isomeric mustard-oil prevailed.—L. Nilson has studied the selenites of beryllium, lanthanium, cerium, didymium, yttrian, erbium, and yttrium. The former metal appeared to enter into the salt as a diad, the rest as triads; thorium as a tetrad.—V. Hæmilian has proved the presence of a considerable portion of ordinary alcohol in commercial methylic alcohol.—L. Pfaundler stated the influence various solvents have on the proportion in which a base is divided between two acids.—W. Ebstein and J. Müller have isolated the ferment contained in the liver and found its action on glycogen to disappear not only when phenol but when the trace of any acid was added.—O. Fischer has transformed methyl-anthracen into methylalizarine, $C_{15}H_{10}O_4$.—A. Ladenburg observed the action of acetic acid on diamines to consist in the formation of ethenyl compounds:

$$\underset{\text{Toluylendiamine.}}{C_7H_6(NH_2)_2} + C_2H_4O_2 = \underset{\text{Ethenyltoluylendiamine.}}{C_7H_6N_2HC_2H_3} + 2H_2O.$$

—V. Meyer and W. Michler, by treating disulphobenzolic acid with cyanide of potassium and potash, have obtained both terepthalic and isophthalic acid in the same reaction.—Drs. von Mering and Musculus, after giving large quantities of chloral to patients, have found an acid in the urine of the composition $C_7H_{12}Cl_2O_6$. They deny the decomposition of chloral into formic acid and chloroform to take place in the human system.—P. T. Austin, treating chloronitrobenzol $C_6H_3(NO_2)_2Cl$ with ethylate of sodium, has obtained the ether $C_6H_3(NO_2)_2OC_2H_4$.—A. W. Hofmann has observed the following reaction of cyanogen on mercaptans $RSH + CN_2 = CNH + R - S - C \equiv N$. Where R is $= C_3H_5$ allyl, the sulpho-cyanide is first obtained, which at ordinary temperatures passes into the isomerical oil of mustard.—R. Lussy has been able to combine one molecule of toluylene-diamine with two molecules of phenyl-iso-sulphocyanate. The compound diphenyl-toluylen-sulphurea, when treated with hydrochloric acid, yields aniline and the mustard-oil of toluylene $C_7H_6''(NCS)_2$.

BOOKS AND PAMPHLETS RECEIVED

BRITISH.—A Sketch of Philosophy: J. G. Macvicar, LL.D., D.D. (Wm. Blackwood and Sons).—Wanderings in the Interior of New Guinea: Capt. J. A. Lawson (Chapman and Hall).—The Chemistry of Light and Photography in its applications to Art, Science, and Industry: Dr. Hermann Vogel (H. S. King and Co.)—Fourth (December 1872 to December 1873) and Fifth (December 1873 to December 1874) Annual Reports of the Wellington College Natural Science Society.—Vestiges of the Molten Globe: William Lowthian Green (E. Stanford).—The Native Races of the Pacific States. Vol. ii.: Hubert Howe Bancroft (Longmans).—The Province of Psychology—the Inaugural Address at the First Meeting, April 14, 1875, of the Psychological Society of Great Britain, by the President, Mr. Serjeant Cox.—On the Distribution of Rain over the British Isles during the Year 1874. THURSDAY, MAY 27, 1875

THE ARCTIC EXPEDITION

According to present arrangements, the Arctic Expedition leaves our shores on Saturday next. We feel that this event is one of no ordinary scientific importance, and indeed that it is significant, in a high degree, of a change which has come over the ideas of the governors and the governed alike in this country.

While prior Expeditions have advanced knowledge on their way to a high northern latitude, the present one sails to a high northern latitude for the purpose of advancing knowledge. We believe that the Admiralty authorities are fully aware of the importance of this distinction, and that when the final Instructions about to be issued to Capt. Nares are published, it will be seen that although they have been compelled to lay down a route and to state a goal to be reached if possible, the advancement of natural knowledge as opposed to mere topography is recognised as the main object.

All the best hearts in Britain will beat higher at the thought of this noble British attempt to drive still further back the boundaries of the unknown and the unexplored in spite of the obvious perils with which the attempt is surrounded. The work is undoubtedly one of difficulty, and although a combination of past experience and present discipline may be regarded as certain to restore to us at some future day the gallant men now aboard the *Alert* and *Discovery*, it is almost too much to hope that both the ships will run the gauntlet of the ice-barriers both out and home. Capt. Nares, we presume, has, as the Admiralty Arctic Committee recommended, full authority to abandon the *Alert* in 1877 if the exploration in 1876 has been final or her escape be doubtful, and the possible abandonment of both ships is contemplated in the Committee's Report: this shows that the Admiralty has counted the cost, and the fact that the Expedition sails shows us how the benefit resulting from scientific inquiry is acknowledged by the Government.

Were the officers of the ships less devoted to the scientific side of their work, or less capable of undertaking it than they are, they might be fairly alarmed at the parting gifts of the men of science which they have received this week in the shape of Instruments of all kinds, a special Arctic Manual of Scientific Inquiry of some eight hundred pages, and Scientific Instructions in the branches of work to which the Council of the Royal Society attaches the highest importance. The Manual, which has been edited by Prof. Rupert Jones on the biological, and by Prof. W. G. Adams on the physical, side, is supposed to contain the most important information already acquired on the various inquiries to be prosecuted; the Instructions being intended to show in what direction and in what manner this information can be extended.

A glance at the Manual and Instructions, to which we shall take occasion to refer more at length on a subsequent occasion, will make many regret that they are not among those who, if they are incurring risk and undergoing privations, will, during the greater part of their absence, be living in a new world of surpassing interest from a scientific point of view, as well as of soul-stirring grandeur, not unmixed with awful beauty; a world in which there is almost a new astronomy, where even the colours of the sky are different, and where not only the physicist but the biologist finds fresh wonders at every step.

The Hydrographer of the Admiralty, Capt. Evans, has made a noble contribution to the volume of Instructions, in the shape of three provisional maps of the Magnetic Elements, not only over the whole of the region to be explored, but including Greenland and part of the region to the west of Baffin's Bay and Davis' Strait. The various inquiries to be prosecuted by the officers and the naturalists of the Expedition, Capt. Feilden and Mr. Hart, are dealt with in the Instructions, among others, by Profs. Stokes, Sir Wm. Thomson, Adams, and Tyndall, the Hydrographer, Mr. Hind, Mr. Spottiswoode, Dr. Haughton, Mr. Scott, Dr. Rae, and Mr. Lockyer, on the physical side; and by Dr. Hooker, Profs. Huxley, Allman, Flower, Maskelyne, Ramsay, and Roscoe, Dr. Günther, Mr. Gwyn Jeffreys, Mr. J. Evans, and Mr. Judd on the biological, geological, and mineralogical sides.

Looking at the contents of the Manual, every possible source of information in Arctic Biology, Geology, and Physics would seem to have been ransacked, and the result is a volume which must be of the highest value, not only to those whose only text-book it will be for the next two or three years, but to all who wish for the best information about the region for which the envied explorers sail on Saturday. Among those whose contributions have been printed in the biological department will be found such names as those of Lütken, Mörch, Giesecké, Hooker, Heer, Nordenskjöld, Huxley, E. Forbes, and many others.. All the most notable Arctic explorers have been drawn upon, from Sabine and Parry down to Payer and Weyprecht; while contributions will be found from many of the greatest living authorities on such subjects as Meteorology, Physical Properties of Ice, Tides and Currents, Geodesy and Pendulum Experiments, Terrestrial Magnetism, and the Aurora.

It will be sufficiently evident, therefore, that those men of science who were anxious for Arctic exploration, and on whose recommendation the Government have fitted out the Expedition, have done all in their power to make it as complete as possible. The sending of the *Valorous* to Disco with the *Alert* and *Discovery* will not only enable it to start under the best conditions, but will enable a new lustre to be added to the whole attempt, in the shape of biological and temperature observations in the waters passed through on the return journey, waters which up to now have never been explored. For this we have to thank Mr. Gwyn Jeffreys, for unless he had volunteered to superintend these researches, they certainly would never have been made. It is to be hoped that the authorities have not been unmindful of the importance of at least duplicating all observations as soon as they are made and of depositing them in safe places, so that whatever may be the fate of the ships, the loss to science shall be reduced to a minimum.

Capt. Nares and those who accompany him may be assured that though they will be lost to sight for a long time to come, they will be by no means forgotten, all will wish them success, and every hint of news will be eagerly welcomed. May the two crews return "all told."

SACHS'S "TEXT-BOOK OF BOTANY"

Text-book of Botany, Morphological and Physiological. By Julius Sachs, Professor of Botany in the University of Würzburg. Translated and annotated by Alfred W. Bennett, M.A., B.Sc., F.L.S., assisted by W. T. Thiselton Dyer, M.A., B.Sc., F.L.S. (Oxford: at the Clarendon Press, 1875.)

IN 1868 the first edition of Dr. Sachs's "Lehrbuch der Botanik" appeared in Germany; a second edition was soon called for, and it appeared in 1870; the third was published in 1873, and the fourth was issued about the end of 1874. The third edition was translated into French and annotated by M. Ph. van Tieghem, and now we have an English translation of the same edition from the hands of Messrs. Bennett and Dyer.

The want of a good text-book of Botany, one that would give an accurate idea of the present state of botanical science, has long been felt by English students. We therefore heartily welcome the appearance of the English translation of Sachs's "Lehrbuch der Botanik," because we feel certain that it will supply that want so long felt, and be of the greatest value to both teachers and students. Our text-books had mostly fallen behind the time, the older ideas and theories were still retained instead of being swept away to make room for new facts or for the more correct interpretation of long-known but imperfectly understood phenomena. The illustrations of the older works were often defective, frequently absolutely incorrect, and yet they descended from text-book to text-book with unfailing regularity. Terms were multiplied needlessly, without any correct appreciation of the facts to be indicated by them; lectures became a mere illustrated botanical glossary, the biology and physiology of plants were almost entirely neglected, and the science rendered as repulsive as possible. In the work now before us we have a text-book of Botany which the teacher can confidently recommend to the student as being an excellent guide; as giving an extensive and trustworthy account of the present state of botanical science in Europe; and while it indicates the theories and problems at present occupying the attention of botanists, it points him to the subjects which will best repay the original investigator. The illustrations form an important feature in the work, most of them being original, and the result of laborious investigation: if borrowed, it was only when the objects were inacessible, or because it seemed impossible to give a better than the figure already in use. This gives a freshness to the book, which is a charm in a text-book of Botany.

Prof. Sachs's work is devoted exclusively to Morphological and Physiological Botany, and therefore differs in its scope from the text-books to which botanical students in this country are accustomed. The whole work is divided into three books. Books I. and II. treat respectively of General and Special Morphology, Book III. being devoted to Physiology. No exhaustive account of the characters of the natural orders of flowering plants is given, a feature which at once places Sachs's text-book in marked contrast to our English ones. All that is given is an enumeration of the orders and families according to the systems recently proposed by Braun and Hanstein. But the want of characters of orders and families cannot be felt by the English student, as he can consult the admirable translation of Le Maout and Decaisne's "Traité Général de Botanique," and there get all he can possibly want. Indeed, we may look upon Sachs and Le Maout and Decaisne as forming a complete work, the one treating fully of such parts of botany as are omitted or only very imperfectly dwelt upon by the other.

The General Morphology of Plants is treated of by Sachs in the three chapters forming the first book. The first chapter deals entirely with the morphology of the cell, and is a most exhaustive treatise on the subject. In describing the nature of the cell, Sachs says: "By far the largest proportion of cells in the living succulent parts of plants, *e.g.* young roots, leaves, internodes, fruits, are seen to be made up of three concentrically-disposed layers; firstly, an outer skin, firm and elastic, the cell-membrane or cell-wall, consisting of a substance peculiar to itself, which we call cellulose. Close up to the inner side of this entirely closed membrane is a second layer, also entirely closed, the substance of which is soft and inelastic, and always contains albuminous matter; H. von Mohl, who first discovered this substance, gave it the very distinctive appellation of Protoplasm. In the condition of cells now under consideration it forms a sac enclosed by the cell-wall, in which usually also other portions of protoplasm are present in the form of plates and threads. Absent from some of the lowest organisms, but present in all the higher plants without exception, there lies imbedded in the protoplasm a roundish body, the substance of which is very similar to that of the protoplasm—the nucleus. The cavity enclosed by the protoplasm sac is filled with a watery fluid, the cell-sap. And besides this, there are also very commonly found in the interior of the cell granular bodies, which, however, may be passed over for the moment." Following this we have an account of the formation of cells, and then the cell-wall, the protoplasm, nucleus, granular and other substances contained in the protoplasm, cell-sap and crystals are each described in turn. The union of cells to form tissues is next described, and Sachs gives us a three-fold division of tissues into epidermal, fibro-vascular, and fundamental or "ground tissue." The section devoted to Primary Meristem and the apical cell will be read with interest, and the facts there stated will probably be new to most English readers.

The Morphology of the External Conformation of Plants is treated of in the last chapter of the first book. In English text-books much space is devoted to "Organography," the physiological method of study being chiefly adopted. Sachs, however, draws a wide distinction between members and organs, and in the section on Metamorphosis shows that all "organs" may be referred to a few original forms. The original forms or morphological members are only five in number, viz., Thallome, Caulome, Phyllome, Trichome, and Root. These members do not perform any functions, but they are capable of being "adapted" or metamorphosed into "organs" performing many very different functions. Take the adaptations of a Phyllome or leaf-member as an illustration of this. Sachs mentions that "the thick scales of a bulb, the skin-like (not "cuticular," as given in the English translation, p. 129, top line) appendages of many tubers, the parts of the calyx and corolla, the stamens and

carpels, many tendrils and prickles, &c., are altogether similar (in mode of development) to the green organs which have been termed simply leaves." So with all the other members; they may be modified to perform the most varied functions.

The second book, treating of Special Morphology and outlines of Classification, will probably be found to be the most generally interesting part of the work. It gives a clear and valuable account of all the "classes" of the vegetable kingdom, which, according to our author, are *thirteen* in number, and are to be further arranged in five groups, viz., Thallophytes, Characeæ, Muscineæ, Vascular Cryptogams, and Phanerogams. Here the industry and care of the author are well shown, as he has collected from all trustworthy sources, descriptions of the structure and life-history of typical forms of plants. This classification is slightly modified in the appendix, which is taken from the fourth edition. The distinction between the Algæ and Fungi, namely, that the Algæ contain chlorophyll, while the Fungi do not, is disregarded, and the Algæ, Fungi, and Characeæ made into four classes, the characters being taken from the modes of sexual reproduction. It seems a pity that the division of the Vascular Cryptogams into classes was not reconsidered, as the discovery of the prothallium of Lycopodium breaks down the division into isoporous and heterosporous groups. We prefer a division of the vascular cryptogams into three classes: Filicinæ, Equisetaceæ, and Lycopodinæ. The Filicinæ include four orders—Filices, Marattiaceæ, Ophioglossaceæ, and Rhizocarpeæ—while the Lycopodinæ include three, viz., Lycopodiæ, Selaginellæ, and Isoeteæ. The chapter on the groups of flowerless plants are of great interest, and will be studied with pleasure by those who have only seen the meagre and often untrustworthy account given in some of our text-books.

Passing to the Phanerogams, Sachs considers the distinguishing characteristic of the group to be the formation of the seed. He contrasts the Cryptogams and Phanerogams, and points out the homologies of the reproductive organs. "This organ (the seed) is developed from the ovule, which, in its essential part, the nucleus, produces the embryo-sac, and in this the endosperm and the embryonic vesicle. The latter is fertilised by the pollen-tube, an outgrowth of the pollen-grain, and, after first growing into a pro-embryo, produces the embryo. The phanerogamic plant, which is differentiated into stem-leaves, roots, and hairs, corresponds to the spore-forming (asexual) generation of vascular cryptogams; the embryo-sac to the Macrospore: the pollen-grain to the Microspore: the endosperm is equivalent to the female prothallium; and the seed unites in itself, at least for a time, the two generations, the Prothallium (endosperm) together with the young plants of the second (sexual) generation (the embryo)." Throughout the whole of the chapters of the second book, the influence of the "Theory of Descent" is very evident. Sachs, however, withdraws, in the fourth edition, the pedigree of the vegetable kingdom, which he sketches in Book III. of the present edition. The Phanerogams are divided into three classes, Gymnosperms, Monocotyledons, and Dicotyledons. Our author adheres mainly to the Gymnospermous theory, and certainly the question whether conifers are gymnospermous or not has yet to be decided, notwithstanding the recent controversy of Eichler and Strasburger.

More than one hundred pages are devoted to the Angiosperms, Monocotyledons, and Dicotyledons. In the remarks on the flowers of Angiosperms, many of our long-cherished ideas, the arrangement of stamens, for example, are rudely disturbed. Monadelphous stamens, as in *Malvaceæ*, are shown to be the result of cohesion of primordial stamens, and subsequent branching. The Polyadelphous stamens of Hypericum are formed by branching of three or five primordial stamens. The use of the English terms "regular" and "symmetrical" as applied to flowers, has been a cause of trouble to the translators, and we cannot but express the hope that both these terms may be quietly dropped into oblivion. On the subject of placentation, the statements of Sachs differ from those usually taught in this country. He shows the relation between the parietal and axile forms, and, making two divisions—viz., the ovules produced by carpels, and the ovules produced on the axis—further subdivides both of these into two:—

1. Marginal. Ovules for reflexed margins of carpels.
2. Superficial. Ovules for whole inner surface of the carpel, except on midrib.
3. Lateral. Ovules produced singly or in numbers from floral axis.
4. Terminal. Apex of axis bearing nucleus of ovule.

The formation of the embryo is very carefully described from Hanstein's researches, and the three layers of tissue in the embryo, Dermatogen, Periblem, and Plerom, carefully figured. The great significance of these layers has probably not yet been fully appreciated, and if it holds that axial structures arise from plerom and lateral appendages from periblem tissues, then a most important guide will be obtained enabling us to determine accurately the morphological value of many disputed structures.

In the classification of inflorescences we have Schimper's term Dichasium substituted for the incorrect "dichotomous cyme" used in English works. This is a marked improvement, as it was always a difficulty to the student to find that, although called dichotomous, it was not so. There is also a great difficulty with the terms helicoid and scorpioid. Sachs uses Schimper's terms bostryx and cicinnus. De Candolle, in 1827, used the term scorpioid to distinguish the characteristic inflorescence of Myosotis, the scorpion grass. The recent researches of Kaufmann, Warming, and Kraus, show that the inflorescences of Borragineæ are sympodial arrangements of dichotomies; and we do not think there would be any difficulty in retaining the term scorpioid for them. Bostryx and cicinnus were used by Schimper in 1835, while it was not till 1837 that the brothers Bravais amended De Candolle's definition of scorpioid and introduced the term helicoid. Schimper's terms, therefore, have the priority, and ought to be used. (See Hofmeister's "Handbuch der Phys. Botanik," vol. i. p. 434).

The floral diagrams given by Sachs will be found very useful, and we also think that the adoption of the floral formulæ will be a great assistance to the student. Sachs uses the collective terms for the whorls throughout in his floral formulæ—calyx, corolla, androecium, and gynoecium, while the translators have substituted the name of the

individual member of each whorl, sepal, petal, stamen, carpel. This, we venture to think, is a mistake. We have now used for some time the contractions Ca. Co. An. Gn., which we prefer, the only objection being that this formula contains eight letters instead of five.

Many and great difficulties must have been encountered in translating the second book, and these difficulties seem to have been successfully overcome. We have no doubt that further experience will suggest changes and improvements even in the admirable book now before us.

The third book treats of Physiological Botany, and is divided into seven chapters. The first chapter is devoted to the molecular forces in the plant, and the second to the chemical processes in the plant. Naegeli's theory that organised bodies consist of isolated particles or molecules between which water penetrates is here fully described, and the value of the theory in explaining nutrition and growth by intussusception pointed out. The movements of water and gases in plants are also treated of in this chapter. The second chapter deals with the elementary constituents of the food of plants, assimilation and metastasis, and respiration in plants. Sachs describes the separation of oxygen and fixation of carbon as assimilation, and limits the application of the term respiration to the taking up of oxygen and liberation of carbon dioxide. The influence of external conditions, as temperature, light, electricity, and gravitation in plants, forms the subject of the third chapter. The mechanical laws of growth, including the movements of growing parts, are fully described in chapter iv. This chapter will be read with much interest, and many of the statements will be found to be new to English students. The fifth chapter gives a careful *résumé* of what is known regarding the movements met with in full-grown parts of plants, whether periodic or dependent on the action of stimuli. Chapter vi. is devoted to the phenomena of sexual reproduction, the sections on the influence of relationship on sexual cells, and on hybridisation being of much importance. The last chapter is devoted to the origin of species, to varieties, and to the Theory of Descent.

In closing the book after giving the above brief sketch of its contents, we cannot but express our satisfaction at the manner in which Messrs. Bennett and Dyer have done their work. The notes appended to the English edition are of much value, and will assist the student in his studies. We have but one objection to the work, and that is its high price as compared with the German edition. Surely the price will be an obstacle in the way of its extensive circulation. Could anything be done to obviate this? Sachs himself has already issued the physiological portion of the third German edition separately. Why not permit students to obtain one or other of the three books separately? Or might not an abridgment be made, somewhat on the principle of Prantl's Lehrbuch? As a text-book it must exercise a most powerful influence on botanical teaching in this country, and while it will supersede all other text-books for advanced students, we fear that its size and price may prevent it being so widely used as it ought to be. With Sachs' text-book within reach, teachers and students will be themselves to blame if they are behind the time in botanical science. Then, the English edition being translated from the third German edition, students can readily keep up their knowledge, because the "Botanischer Jahresbericht," beginning as it does in 1873, will refer them to all the more recent literature. While we have thus expressed our entire satisfaction with the work of the translators and annotators, let us not forget to mention that the way in which the work is got up does credit both to the Clarendon Press and Messrs. Macmillan and Co.

W. R. M'NAB

DR. CHAMBERS'S "MANUAL OF DIET"

A Manual of Diet in Health and Disease. By T. King Chambers, M.D. (Smith, Elder, and Co., 1875.)

THERE are many writers who, immediately they place pen to paper, seem to be affected with a certain formality of diction and severity of style which prevents them doing justice to their subject in the eyes of the more easily satisfied public, who, while desiring instruction, prefer it to be mixed with a certain amount of that form of interest which can be given it by an apparent "at homeness" on the part of the author. Dr. Chambers does not suffer from this fault. In the work before us he has produced one of the most readable as well as practical manuals on diet which we could want to see. The interest is maintained from beginning to end, and much valuable information is given on many of the important topics of everyday life without the uncomfortable sensation of any effort being needed to obtain it.

The subject is treated of under three headings: General Dietetics, Special Dietetics of Health, and Dietetics in Sickness. The author commences with the question—What is the natural food of man Flesh-eating animals have teeth, jaws, and limbs suitable for capture and tearing, vegetable feeders have bulky viscera, and so on. Applying similar arguments to the human race, "to judge by form and structure alone, the natural food of an adult man must be pronounced to be *nothing*;" from which we must necessarily deduce, as is indicated by other considerations, that man as man assumed his special characters *after* he commenced the employment of instruments for offence and defence. In fact, the developed heel, with which is correlated the non-arboreal habit, is incompatible with the naturally defenceless condition of our species.

The space which is gained by the omission of the chapters on the chemistry, botany, &c., of food stuffs to be found in most works on diet and food, is, as we are told in the preface, employed in a full discussion of many matters connecting food and drink with the daily current of social life. The number of observations which will come home vividly to almost anyone turning over the pages of this work is so numerous that we think a few quotations will give the best idea of their scope. For instance, salads form an important article of diet in every family. "The salad ought to be dressed by one of the daughters of the house, after she has herself dressed for dinner, singing, if not with voice, with her clean, cool fingers, sharp silver knife, and wooden spoon—

> "Weaving spiders, come not here;
> Hence, you long-legged spinners, hence:
> Beetles black, approach not near;
> Worm nor snail, do no offence."

Since the introduction of railways the difficulty in procuring good mutton is acutely felt in all but large cities, and the author makes a suggestion which, where carried

out, would much reduce the inconvenience. He recommends those who can do so "to join a 'mutton club,' buying the lambs of a full-sized breed, and keeping them to at least three-and-a-half years old before killing. The price per pound will not be less than charged by the butcher, but it will supply an article twice as good as his." The remarks with reference to eggs are also very much to the point. "High game has fortunately gone out of fashion, and the most frequent form in which we now meet with decomposing albuminoid matter is that of a fusty egg. Some housekeepers seem to consider this quite good enough for made dishes, and thus spoil material worth ten times what they save by their nasty economy. No egg should be allowed to enter the kitchen that has the slightest smell of rotten straw."

In accordance with the opinion of most of the medical profession and of a large body of the public, we read that "as a regular beverage for a healthy person there is no wine in the English market equal to claret." No doubt the statistics of a few years hence will prove that the present reaction against port and sherry will make itself evident in the considerable diminution of the number of those who are liable to be attacked with the gout, and so demonstrate the advantages of the lighter wine.

In the section on the special dietetics of health many important remarks are to be found. Hints are given to those who pursue the commercial, the literary, and professional life, special chapters being devoted to each. The regimen of infancy and motherhood, of childhood and youth, are not omitted. Dr. Chambers is not the only author who inveighs against afternoon tea, and we cannot agree with the argument on which his objections are based. He tells us that "the dilution and washing away of the gastric secretion weakens its power of digesting the subsequent dinner, improperly blunts the appetite, and not unfrequently generates flatulence and dyspepsia." But the gastric juice is not secreted if solid food is not taken, and any fluid introduced into the stomach can hardly but be absorbed within a quarter of an hour or so. The substitute suggested, "a biscuit, and an orange or an ice," is, in our estimation, much more injurious.

Over thirty pages are devoted to the question of the value of alcohol, the results being too lengthy to summarise on the present occasion. They are well worth reviewing. "Some well-meaning persons think to discourage intemperance in drink by affecting a cynical carelessness as to the quality of that which is consumed. . . . However little a man's purse allows him to drink, let it be good."

The question of the dietetics of disease will appeal to all who have the charge or any interest in those who are invalided. They bear the same practical impress as the other portions of the work. Though some of the author's suggestions may appear to be founded on a somewhat dogmatic basis, they all have an element of truth in them which may lead the reader to think twice of the reasons why he is accustomed to adopt any line of action which may be directly opposed to them.

OUR BOOK SHELF

An Elementary Exposition of the Doctrine of Energy. By D. D. Heath, M. A., formerly Fellow of Trinity College, Cambridge. (Longmans, Green, and Co.)

In this book we have a very good elementary exposition of the Doctrine of Energy; perhaps, however, better adapted for the use of schools than for the general public. Indeed, we are told in the preface that the work was developed from a set of lectures given to the senior classes of Surrey County School. In his discussion of fundamental units the author makes some very good and original remarks. He tells us, for instance, in connection with the first law of motion, that "the *rate* and the *direction* of motion with and in which (respectively) a body is moving at any moment is to be considered as part of its *actual condition* at that moment, which it will retain until some adequate cause changes either the velocity or the direction, or both. We may reasonably inquire *how it got* the motion it has, as we may how it came by its shape or its temperature; and again, under what circumstances it will change any of these properties; but not *why*, having got them, it keeps them."

After dismissing the subject of fundamental units, the writer goes on to dynamical energy, a subject which is fully and fairly discussed. The author next proceeds to thermal and other energies, and ends by a brief account of molecular theories. If we have any fault to find, it is that undue preference seems to be given to the British system of units, while the decimal system is overlooked.

We think, too, that in the introductory part of the work the author is not very clear in his statement with regard to energy, where he tells us we may define it to be "the capacity or power of any body or system of bodies, when in a given condition, to do a certain measurable quantity of work; that is, to change its own condition and that of other bodies, exhausting its power by the using of it." We think that the second part of this definition might have been omitted with advantage.

The author, as he tells us in his preface, has endeavoured to give the young student some conception of the *possibility* of explaining the conservation of energy by the theory that all phenomenal changes are really in themselves changes of motion and position among the molecules or ultimate atoms of substances; and he adds the hope that he has succeeded in presenting this as exhibiting a probable surmise, which may be false without vitiating the doctrine previously developed.

This strikes us as being very well put. The conservation of energy would hold if we imagine the universe to be composed of ultimate atoms with forces acting in lines between them; but should it be found that this last conception is inapplicable to portions of the universe, as, for instance, the medium which conveys light, nevertheless it does not follow that the conservation of energy does not still hold true.

The Commercial Handbook of Chemical Analysis. By A. Normandy. New edition, enlarged, by Henry M. Noad, Ph.D., F.R.S. (London: Lockwood and Co., 1875.)

When the late Dr. Normandy first published his work on Commercial Analysis the Adulteration Act did not exist, and the book was chiefly used by chemical manufacturers and by the small class of practical analysts. Dr. Noad's enlarged edition of the work appears very opportunely, and it will be found to be essential to the analysts appointed under the new Act. It contains, in alphabetical order, a concise list of all ordinary substances which can require to be analysed in connection with food and drink, and in addition the methods of analysing many substances which can only be required in special manufactures, or are only used as drugs. Each article commences with an account of the substance in its pure state: this is followed by a list of the most common impurities or adulterations, and then by the best means of detecting them. The adulterations of some common commodities are somewhat startling; thus, bread may contain rye and barley flour, oatmeal, pea and bean meal, potato starch and rice flour, while of mineral constituents there may be lime, alum, magnesia, ground soapstone,

and sulphate of copper. The substances sometimes employed to colour sweetmeats, liqueurs, jellies, &c., include some of the most fatal poisons, such as the acetate, arsenite, and carbonate of copper, chromate and iodide of lead, and the sulphides of arsenic and mercury. Indeed, we well remember going over a sweetmeat manufactory, and on remarking on the bright yellow colour of some large comfits we were told that chrome yellow was employed to produce it, our informant evidently having no idea that the substance is a most virulent poison. A long article is devoted to the adulteration and fabrication of wines, and the "plastering" and "fortifying" of sherries is discussed at length. In all cases the most recent results are given, and the work is well edited and carefully written. A glossary at the end of the book will be found useful both to the analyst and the student.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

"The Unseen Universe"

WE have read with satisfaction (NATURE, vol. xii. p. 41), your very candid and fair *précis* of our recent work, "The Unseen Universe." There are, however, one or two comments added in which the writer seems to have misapprehended our meaning, possibly from the fact that in the first edition of such a work the arrangement may be regarded as not having quite taken its final shape.

To begin, we fail to understand what the reviewer means when he says, "It is a mere theological dogma to say that what energy perishes in the visible passes into the invisible universe; and the dogma is worthless as a physical principle on which to build any physical reasoning."

Our views will be found on p. 159 of our book: "*May we not say that when energy is carried from matter into ether it is carried from the visible into the invisible?*" Surely the ether may be looked upon as forming part of the invisible universe, and also as having received a large portion of the energy which was once attached to visible matter.

Our object was to show that we introduced no new dogma inconsistent with the received ideas regarding energy, inasmuch as these contemplate an invisible universe as truly as we ourselves do.

The second point upon which we would remark is the assertion of the reviewer that by regarding the visible universe as an infinite whole, the arguments on which its end and its beginning are inferred seem to vanish. In reply to this we would remark, that even allowing (which we are not disposed to allow) that the visible universe is infinite, this would not affect our argument against its past eternity. Our argument (see p. 127 of the book) is, that *the dissipation of the energy of the visible universe proceeds*, pari passu, *with the aggregation of mass, and the very fact therefore that the large masses of the universe are of finite size is sufficient to assure us that the process cannot have been going on for ever.*

THE AUTHORS OF "THE UNSEEN UNIVERSE."

Sense of Humour and Reason in Animals

IN the recently published edition of the "Descent of Man" there is some additional matter concerning the above subjects, and as the following illustrative cases fell under my own observation, I think it is worth while to publish them as supplementary to those adduced by Mr. Darwin.

Several years ago I used to watch carefully the young Orang Outang at the Zoological Gardens, and I am quite sure that she manifested a sense of the ludicrous. One example will suffice. Her feeding-tin was of a somewhat peculiar shape, and when it was empty she used sometimes to invert it upon her head. The tin then presented a comical resemblance to a bonnet, and as its wearer would generally favour the spectators with a broad grin at the time of putting it on, she never failed to raise a laugh from them. Her success in this respect was evidently attended with no small gratification on her part.

I once had a Skye terrier which, like all of his kind, was very intelligent. When in good humour he had several tricks, which I know to have been self-taught, and the sole object of which was evidently to excite laughter. For instance, while lying upon one side and violently grinning,* he would hold one leg in his mouth. Under such circumstances nothing pleased him so much as having his joke duly appreciated, while if no notice was taken of him he would become sulky. On the other hand, nothing that could happen displeased him so much as being laughed at when he did not intend to be ridiculous. Mr. Darwin says:—"Several observers have stated that monkeys certainly dislike being laughed at" (p. 71). There can be little or no doubt that this is true of monkeys; but I never knew of a really good case among dogs save this one, and here the signs of dislike were unequivocal. To give one instance. He used to be very fond of catching flies upon the window-panes, and if ridiculed when unsuccessful, was evidently much annoyed. On one occasion, in order to see what he would do, I purposely laughed immoderately every time he failed. It so happened that he did so several times in succession—partly, I believe, in consequence of my laughing—and eventually he became so distressed that he positively *pretended* to catch the fly, going through all the appropriate actions with his lips and tongue, and afterwards rubbing the ground with his neck as if to kill the victim: he then looked up at me with a triumphant air of success. So well was the whole process simulated, that I should have been quite deceived, had I not seen that the fly was still upon the window. Accordingly I drew his attention to this fact, as well as to the absence of anything upon the floor; and when he saw that his hypocrisy had been detected, he slunk away under some furniture, evidently very much ashamed of himself.

The following example of *reason* in a dog is the most striking that has ever fallen within my personal observation. A son of the above-mentioned terrier followed a conveyance from the house at which I resided in the country, to a town ten miles distant. *He only did this on one occasion*, and about five months afterwards was taken by *train* to the same town as a present to some friends there. Shortly afterwards I called upon these friends in a different conveyance from the one which the dog had previously followed; but the latter may have known that the two conveyances belonged to the same house. Anyhow, after I had put up the horses at an inn, I spent the morning with the terrier and his new masters, and in the afternoon was accompanied by them to the inn. I should have mentioned that the inn was the same as that at which the conveyance had been put up on the previous occasion, five months before. Now, the dog evidently remembered this, and, reasoning from analogy, inferred that I was about to return. This is shown by the fact that he stole away from our party—although at what precise moment he did so I cannot say, but it was certainly *after* we had arrived at the inn; for subsequently we all remembered his having entered the coffee-room with us. Now, not only did he infer from a single precedent that I was going home, and make up his mind to go with me; but he also further reasoned thus:—"As my previous master lately sent me to town, it is probable that he does not want me to return with him to the country: therefore, if I am to seize this opportunity of resuming my poaching life, I must now steal a march upon the conveyance. But not only so, my former master may possibly pick me up and return with me to my proper owners: therefore I must take care only to intercept the conveyance at a point sufficiently far without the town, to make sure that he will not think it worth his while to go back with me." Complicated as this train of reasoning is, it is the simplest one I can devise to account for the fact, that slightly beyond the *third* milestone the terrier was awaiting me—lying right in the middle of the road with his face towards the town. I should add that the

* This habit of violently grinning is not, I believe, uncommon among Skye terriers—the pure original breed of Skyes, I mean, and not the broad-nosed shaggy-coated animals which have almost supplanted them. The habit is very remarkable, for there can be no doubt, I think, that it is intended to imitate laughter. Many intelligent dogs understand the meaning of laughter as implying good humour. I have a setter just now, which always rouses up and whines for admittance to a room when he hears a good laugh going on, wagging his tail the while, in proportion to the varying intensity of the laughter; but I do not know of any other breed of dogs which actually *imitates* it—at all events not with such evident purpose as do Skye terriers. The purpose is evident, not only because the gesture is never made at any other time than when the animal wishes to be particularly agreeable; but also because the grin is carried to a highly unnatural degree—much more, *e.g.*, than the strongest snarl would require; and, which is stranger still, I have frequently seen my terrier on such occasions shaking his sides in a convulsive manner—an action he never performed at any other time.

second two miles of the road were quite straight; so that I could easily have seen the dog if he had been merely running a comparatively short distance in front of the horses. Why this animal should never have returned to his former home on his own account, I cannot suggest; but I think it was merely due to an excessive caution which he also manifested in other things. Be the explanation of this, however, what it may, as a fact he never did venture to come back upon his own account, notwithstanding there never was a subsequent occasion upon which any of his former friends went to the town but the terrier was sure to return with them, having always found some way of escape from his intended imprisonment.

Regent's Park, N.W. GEORGE J. ROMANES

Equilibrium of Gases

IN a former letter (NATURE, vol. xi. p. 486) I ventured to express an opinion contrary to that of most authorities, that the temperature of a vertical column of gas at rest would tend to diminish from below upwards.

I then stated that there was nothing to counteract the tendency to the upward diminution of energy which must result from gravitation. I am indebted to Mr. S. H. Burbury for pointing out to me that a counter-action exists in the removal from the system, at every point of the ascent, of those molecules whose vertical energy at that point is *nil*. The total mean energy of the molecules may thus remain the same, although a constant deduction is made from the energy of every molecule remaining in the system.

Mr. Murphy's argument (NATURE, vol. xii. p. 26) from the absence of cumulus in the Arctic regions, is also a sound one as far as it goes, and fairly counterbalances that derived from tropical calms and storms.

I must therefore withdraw my dissent from the generally received doctrine of the tendency to equality of temperature in a vertical column. R. C. NICHOLS

Athenæum Club, May 20

Contributions to the Natural History of the Wolf (*Canis pallipes*) of Northern India

HAVING had the opportunity of examining a number of wolf-cubs, it may not be without some interest to record my observations in your useful journal.

This year (1874–75) I examined fourteen batches or litters of wolf-cubs between December 18 and February 1. Judging from the apparent ages of the different litters, I should fix the breeding time of the wolf from about the middle of October to about the end of December. But the majority are bred in December, as out of the fourteen batches I could approximately fix the birth of eleven of them in some date of December. On the 29th of December a full-grown she-wolf, in milk, was brought to me, with seven cubs, which appeared to be about a week old. She had ten teats. The eyes and ears of the cubs were closed; their ears were drooping; their general superficial colour was sooty brown, with an under colour, that is, at the roots of the hairs, of dirty light tan. The latter colour was more marked on the head and flanks, while the sootiness was more decided on the hinder part of the body. They all had a milk-white chest-spot varying in size. Six of them had white hairs at the tips of their tails.

All those I examined, of about this same age, had similar characters. When the eyes of young wolves open, and they begin to crawl, about the third week, their general colour is a dirty light tan, washed with soot. As they grow, their ears become erect, their general colour a uniform light tan, with only the tips of the hairs dark, the tail being the darkest part of the animal. After the sixth week or so, the white chest-spot emerges into the light fawn colour of the remainder of the chest, and a dark collar on the under part of the neck becomes visible. This collar looks as if dark grey ashes were brushed across the greyish white of the neck. All those I examined which looked older than four or five weeks had this collar. But it disappears again as the wolf gains its adult colouring, becoming merged into the uniform creamy white of the neck and chest. Out of seventy-nine wolf-cubs which I examined, all but one had a white chest-spot, varying in size from a few hairs to a patch the size of a rupee. Fourteen of them had white tips to their tails, varying in size. Seventeen of them had white tips to one or more of their feet. These white marks leave no doubt about the close relationship between the wolf and the domestic dog. The sex of seventy-four cubs was noted, belonging to thirteen litters. Forty were males, and thirty-four were females. The number of young at a birth was from three to eight.

Lucknow E. BONAVIA

OUR ASTRONOMICAL COLUMN

1 LEPORIS (FL.).—This star is wanting in both Argelander's *Uranometria* and in Heis's Atlas, though the estimations of magnitude are very accordant; indeed, with the exception of Lalande, who calls it $6\frac{1}{2}$ observers including Flamsteed, Bradley, Piazzi, and Johnson appear to have uniformly estimated it . It is 45' *s.p.* ϵ Leporis, a star of the 4th magnitude. Baily has this note: "The star is designated as of the 9th magnitude in the *British Catalogue;* but I apprehend this is a typographical error, as it is stated to be the 6th in the original entry." Yet, the star having been omitted by Argelander, and particularly by Heis, there remains a suspicion of variability of light.

THE COMET OF DECEMBER 1872 (KLINKERFUES—POGSON). The observation of a telescopic comet by Mr. Pogson, at Madras, on the mornings of December 3 and 4, 1872, in consequence of a telegraphic message from Prof. Klinkerfues, of Göttingen, that Biela's Comet had "touched the earth" on November 27, and might be sought for near the star θ Centauri, will be fresh in the recollection of our astronomical readers. The remarkable shower of meteors on that evening had exhibited a radiant almost identical in position, with the diverging point, which meteors moving in the orbit of Biela's Comet would have, and hence the assumption of our close proximity to this body during the meteoric display. Places of the comet detected by Mr. Pogson in the first interval of favourable weather after receiving the telegram were communicated by him in the same month to the Astronomer Royal and Prof. Klinkerfues, but without details of the observations upon which they were founded. With the aid of these positions the question of identity of Pogson's Comet with one of the bodies forming Biela's Comet was examined. There was at the outset this difficulty in the way of entertaining the idea of identity, that if Biela's Comet were actually close to the earth on the evening of November 27, its perihelion passage would have taken place on the 27th of the following month, ten or eleven weeks later than the date indicated by Michez's orbit as perturbed to 1866; nevertheless, since the comet was not detected in 1865-66, in the track it should have followed according to Michez's calculations, though the largest telescopes were employed in a search for it, there remained the possibility of disturbance of the mean motion in 1852, when observations were last obtained, from some unknown cause. Klinkerfues, therefore, assuming the elements of Biela's Comet, examined their relation to Pogson's places, and arrived at the conclusion that the identity of the comet observed at Madras with one of the two Biela comets could hardly be doubted. Subsequently, Prof. Oppölzer, of Vienna, gave attention to the subject: he remarked that with Michez's orbit of Biela, Pogson's observations were not represented upon any supposition as to date of perihelion passage, but with the semi-axis of Biela, and assumed small distances of the comet from the earth at the time of the Madras observations, he deduced several sets of the other elements bearing greater or less similarity to those of Biela, and indicating a very near approach to the earth on November 27th: his conclusion was, that Pogson's Comet stands with high probability in intimate connection with the meteor-shower of that evening; and it is at least possible that the observed object was really one of the heads of Biela.

Since these investigations, the full details of the Madras observations have been published in the *Astronomische Nachrichten*, and Prof. Bruhns, of Leipsic, has

submitted them to very complete discussion, the results of which he has just made known. His inferences are generally opposed to those drawn by Klinkerfues and Oppölzer. With one of the systems of elements given by the latter, he calculates the apparent path of the comet from Nov. 30 to Dec. 8, finding, as was to be expected, a good agreement with Pogson's observations, and with the rate of motion in R.A. given by his comparisons on the first morning, that of Dec. 3, but the ephemeris does not agree with the rate of motion on the following morning, which, Pogson's differences are sufficient to prove, had not diminished. And it should here be observed that the differences of R.A. were evidently obtained with considerable precision, as might be looked for from so practised an observer as Mr. Pogson. The orbit here referred to is as follows:—Mean anomaly, Dec. 3·0 Berlin time, $-5° 6'·8$; longitude of perihelion, 141° 9'; ascending node, 244° 34'; inclination, 10° 28'; angle of excentricity, 54° 17', the semi-axis major being that assigned by Michez for Biela's Comet, and corresponding to a mean daily motion of 530''·1. Again, Bruhns observes that it speaks further against the identity, that by all the ephemerides, at least from Nov. 23 to Dec. 3, the first days in the northern and later in the southern hemisphere the comet should have been more conspicuous than at the time of Pogson's observations, and it is unlikely that it would have escaped notice, particularly in the northern hemisphere. He so far agrees with Oppölzer, that no assumed date for perihelion passage will bring about an agreement of places calculated from the elements of Biela, with those observed; and that an extension of the comet's period of revolution to 2528 days, without a near approach to the planet Jupiter, is most improbable. In Oppölzer's orbit given above, the inclination is 10° 28', while that deduced by Michez is 12° 22'; and to prove that such diminution is not to be accounted for by perturbation during the assumed near approach of Biela to the earth about the time of the meteor-shower, he has calculated the effect of the earth upon the elements of Biela, with the perihelion passage fixed to Dec. 27·75, the epoch which would occasion the nearest approach of the two bodies. The inclination of the orbit to the ecliptic is found to be increased 1'·6 only, the node is advanced 0'·4, the perihelion longitude 7'·3, and the angle of excentricity is diminished 1'·6. The earth's perturbations during such a near approach as is possible in the orbit of Biela (for 1866) would not therefore account for a change of elements sufficient to represent the places of Pogson's Comet. Bruhns then makes two assumptions with regard to the ratio of the curtate distances of the comet from the earth at the times of the Madras observations on Dec. 3 and 4, and in both cases arrives at *retrograde* orbits: the motion of Biela's Comet is *direct*. The first of these orbits from which he computes an ephemeris is as follows (we adapt the longitude of perihelion and the inclination to the catalogue form of expressing them):—Perihelion passage 1872, Dec. 15·3763 Greenwich time; longitude of perihelion, 332° 28'; ascending node, 33° 11'; inclination, 31° 13'; perihelion distance, 0·035205. Hence the track of the comet would be—

12h.	R.A. h. m.	Decl. ° '	Distance from Sun.	Distance from Earth.
Nov. 5	11 10·3	20 13 S.	1·251	1·606
,, 13	11 37·3	23 42	1·073	1·359
,, 21	12 18·1	28 10	0·879	1·118
,, 29	13 27·8	33 14	0·663	0·906
Dec. 3	14 21·5	35 4	0·541	0·828
,, 7	15 30·0	34 50 S.	0·405	0·787

We believe there is little doubt that, so far as can be ascertained from Pogson's two days' positions and the rate of motion indicated by his comparisons, the orbit of the comet observed by him was *retrograde*, and therefore agree with the inference of Prof. Bruhns that it had no relation to Biela's Comet, or, we may add, to the magnificent meteoric display of 1872, Nov. 27, notwithstanding the singularity of its discovery by Pogson, in consequence of the telegram sent to him by Klinkerfues, which was grounded on the opposite opinion.

LECTURES AT THE ZOOLOGICAL GARDENS*

IV.

May 13.—Mr. Garrod on Antelopes and their Allies

THE true Ruminant Animals characterised among Artiodactylate Ungulata by the absence of incisor teeth in the upper jaw, as well as by the possession of a stomach in which three separate compartments, named paunch, honeycomb bag, and reed, are always present,† naturally fall into three different families, the Chevrotains, the Deer, and the Antelopes. The first and last of these remain for consideration.

In the Antilopine, or Cavicorn section, as the latter name implies, the horns are hollow organs. They are epidermic in structure, being composed of hairs agglutinated together to form tubes, which are moulded and fixed upon osseous protuberances of the frontal bones. These "horn cores" are quite different in their nature from the antlers of the deer tribe, as they persist throughout the life of the individual, and are perfectly continuous in their structure with the bones from which they spring. The horns themselves bear much the same relation to the thin layer of vascular membrane which covers the "cores" that the nails on the fingers do to the subjacent soft parts; in the Rhinoceros the horn or horns, though similar in structure, are solid throughout. In many species the horns are present in both sexes, and in one genus (*Tetraceros*) there are two pairs, one attached near the anterior and the other near the posterior margin of the frontal bones.

Many attempts have been made to classify these animals by means of the peculiar structures which are found in some species and not in others. Among the most important of these are the condition of the muffle, or tip of the nose, which is moist in some, as in the ox, and hairy in others, as the sheep. The gland below the eye is also a varying feature, being largely developed in the Indian Antelope, for example, and absent in the Eland. In most species there are two small "false hoofs," remnants of the second and fifth digits, behind the true foot. These, however, are absent in the Royal Antelope and the Pallah. Whether the horns are cylindrical, as in the Chamois, or grooved, as in the Koodo; straight, as in the Oryx, arched, as in the Ibex, or spiral, as in the Markhour; smooth, as in the ox, or transversely ringed as in most, are also tangible characters, by the combination of which with others of less significance various endeavours have been made to arrange the family. These, nevertheless, are none of them satisfactory, on account of the large number of the possible combinations which are to be actually found, at the same time that the relative importance of the different included characters is scarcely capable of being estimated.

There are two animals, the Giraffe of Africa and the Pronghorn, or Cabrit, of the western regions of North America, which are evidently closely allied to the Antelopes, and are probably nothing more than extreme modifications of them. In both, the horn processes or horns are developed in both sexes, at the same time that neither possess false hoofs. The abnormal feature in the Giraffe is found in the horn-like developments, which are pedestals of bone, covered with the ordinary skin of the body, and capped with a tuft of hair. These pedestals, however, differ very materially from those in the Muntjacs among the Deer, and from the horn-cores of the typical

* Continued from p. 28.

† A fourth, the manyplies, is found in all but the Chevrotains.

Cavicornia, in being independent ossifications, situated, on the suture between the frontal and parietal bones instead of simple outgrowths from the frontal only. A median excrescence on the forehead, in front of the above-mentioned processes, is the result of a protrusion upwards of the bones in the part.

The Pronghorn (*Antilocapra*) has well-developed horns. They are attached to ordinary bony cores, exactly similar to those of the Antelopes. They are, however, unique of their kind in that they are branched or bifurcate at their tips, a second smaller point springing from the anterior margin of the flattened stem, and running forward with a gentle curve, convex upwards. In another respect these horns are even more peculiar. Mr. Bartlett, the Superintendent of the Society's Gardens, was the first to show, from a specimen living in the Gardens, that the Pronghorn is in the habit of annually shedding its horns from off their cores. This surprising discovery has since been fully confirmed; at the end of each season the core being found covered with a skin from which the fresh horn is developed.

Respecting the geographical distribution of the Cavicornia, none are to be found in Australasia or in South America. Very few inhabit North America; the Bighorn Sheep, one of the Bisons, the Musk Ox, the Mountain Goat, and the Pronghorn embracing them all. Africa is the head-quarters of the sub-order, and specially of the Antilopine family. In Europe the Bison is a native of Poland, the Chamois and the Ibex of the Alps; whilst the peculiar Saïga reaches our side of the Caspian Sea. Among the best known Indian Antelopes are the Sasin or Antelope *par excellence*, and the Nilghau.

The Chevrotains, or Tragulidæ, form a group of small, deer-like animals, without horns, which were formerly associated with the Musk Deer. The investigations of Prof Flower have, more than any others, proved the independent nature of the group, which approach in their internal anatomy to the Pigs. The third stomach of other Ruminants—the Psalterium—is wanting. In the axis vertebra, the odontoid process, instead of being scooped into a spout, as in the Deer and Antelopes, is peg-like, as in the Swine. The second and fifth metacarpal bones are completely developed from end to end, and the lateral marginal intervals of the upper jaw between the canine and molar teeth are not cut away, as they are in other Ruminants. These and other peculiarities in the teeth, &c., are quite sufficient to divide off the sub-order as an independent one, ranking with the others previously described. The number of genera and species are very inconsiderable, there being two of the former (*Hyomoschus* and *Tragulus*), and not half a dozen of the latter. *Hyomoschus* inhabits Western Africa, occupying much the same ground as does the Chimpanzee. In it the metacarpal bones remain separate during the life of the animal, as in the Swine, and not in the other Ruminants. The fur is spotted like that of most young deer, throughout life. *Tragulus* is found, two species—*T. meminna* and *T. stanleyanus*—in India, the Napu (*T. javanicus*) and one or two others making Java and Sumatra their abode.

RARE ANIMAL AT THE MANCHESTER AQUARIUM

AMONG the numerous new accessions brought together to swell the list of special attractions for the throngs of Whit-week visitors at the Manchester Aquarium, one of the latest arrivals is especially deserving of notice in these columns. This is an example of the so-called "Congo Snake" (*Murænopsis tridactvla*), from the neighbourhood of New Orleans, a singular eel or snake-like animal, belonging, nevertheless, to neither of the classes represented by those two types, but rather to the true Amphibia. Judging from its shape, proportions, and colour, the uninitiated would certainly pass it as an ordinary eel, from which, on closer examination, it will be found to differ in possessing no fins, small bead-like eyes a mere puncture in the place of the ordinary gill-operculum, though more especially in having stationed at each extremity of the attenuated body a pair of feeble little legs, and each leg furnished with three slender toes. These legs may be described as almost rudimentary, but they are at the same time used by the animal, and with more marked effect than might be presupposed, when crawling over the ground at the bottom of its tank. Rising into the midst of the water, it can further swim with great rapidity, progressing then by rapid undulations of its body from side to side, after the manner of a true snake. The length of this specimen is about two feet six inches; greatest diameter, in the centre of the body, one inch and a half, tapering off from the posterior pair of legs into an attenuate and slightly compressed tail. The colour closely resembles that of an ordinary eel, being slate-grey on the dorsal surface and sides down to the lateral line, and below this, ash colour. Along the lateral line is a double row of minute punctures, the orifices, no doubt, of mucous glands similar to those obtaining in true fishes. The animal has to repair to the surface of the water to breathe, but this is at distant intervals, a large quantity of air being drawn through the nostrils into the lung-pouch by a singular inflation of the throat, repeated several times in succession. This specimen is exhibited in one of the octagon table tanks in the centre of the saloon, eighteen inches in depth, so that when taking in its supply of air it does not altogether leave the ground, but raises itself in a semi-erect position until the head touches the surface of the water. With the head just an inch or two below the surface, and standing, as it were, upon its posterior legs, with the anterior pair held out helplessly in the water, is a very favourite attitude with this creature, though at the same time an essentially grotesque one, reminding the observer of the somewhat similar attitude and general appearance, on a colossal scale, of the larva of *Ourapteryx* or other of the Geometria moths. In its native swamps the "Congo Snake" is reputed by the black population to be highly venomous, an injustice to the poor creature as great as when applied by our own benighted countrymen to the harmless Newt or Triton of English ponds and streams, and of which it is merely a highly interesting and most extraordinary exotic type.

We are indebted for this rare and, indeed, at present, we believe, in this country, unique example of this species to Capt. A. H. Mellon, of the Dominion and Mississippi Steamship Company, to whose influential and friendly assistance we are also under further obligations for a fine young alligator some two feet long, the trophy of a preceding voyage. W. SAVILLE-KENT

THE PROGRESS OF THE TELEGRAPH *

VI.

IT has already been observed that from the limited speed on the wire, the development of any extended system of telegraphic communication between the centres of commerce in a country where great distances have to be reached, involves a vast outlay in the duplication of the circuits necessary to afford the requisite transmitting powers, and that by the adoption of the automatic process, in addition to the accuracy of its performance, the greater speed obtained upon long circuits enabled the telegraphic service to be conducted by a much smaller number of wires, thus reducing in a most important degree the outlay of capital expended on con-

* Continued from p. 32.

struction. It is not, however, only by the automatic process that the full transmitting capacity of a conducting wire can be attained. Metallic conductors under certain conditions are capable of transmitting more than one current at the same instant of time, both in the same and in opposite directions; and by a very ingenious system of adjustment of electric resistances and balance of currents, perfected by Messrs. Stearns, Edison, and Prescott, the American electricians, intelligence can be transmitted and recorded over a single wire in opposite directions at the same moment. This system of transmission is known as "Duplex" and "Quadruplex" Telegraphy, and is already extensively employed by the Western Union Telegraph Company in the United States, and over several of the more important circuits in Great Britain. The "Duplex" system is working in America between nearly all the principal cities, and has recently been introduced between Port Hastings, on the island of Cape Breton, where the land circuits are in connection with the submarine cables, and San-Francisco, a distance little short of 5,000 miles. The "Quadruplex" system has been successfully introduced between New York and Boston, with a transmitting capacity upon a single wire equivalent to the transmitting power of four wires worked upon the ordinary Morse system. Thus, by employing arrangements such as the "Duplex" and "Quadruplex," a circuit may be worked either as one wire, or two, three, or four wires, according as the transmitting capacity of the circuit may require to be increased.

As is well known, several sounds may be conveyed at one and the same time by vibrations through a rod without interference, and it is difficult to realise the accuracy with which every vibration is reproduced by anyone who has not witnessed an illustration of the "transmission of sound" by solid conductors. So it is with "Duplex" and "Quadruplex" transmissions through the same wire in opposite directions at the same moment of time; it is equally difficult to realise how distinct signals can be received at either end without interfering with or destroying each other; and yet the principles involved are very simple and easy of explanation.

By the Duplex system, one of the most difficult problems incident to the successful development of telegraphic lines has been solved, namely, how to provide for the annual increase (averaging 20 per cent.) in the amount of business without the annual expenditure on capital account for the erection of additional wires. In the United States, over 150,000 miles of wire are in operation, the rate of increase being something like 20,000 miles per annum, and the Duplex system is capable of doubling the carrying capacity of these wires. The great value of the Duplex system consists in its capability to double the capacity of a wire at any moment, should injury by storm or conflagration interrupt the circuits. By its means, the moment one wire is restored to continuity it becomes equivalent to two, and a second wire raises the carrying capacity of the circuits to four wires, and by skilful manipulation the system may be introduced and adjusted on a circuit in about a minute. From the earliest days of telegraphy it has been well known that two currents, either in the same or in opposite directions, could be passed simultaneously through a conducting wire; indeed, by this means, often has the frame of mind and temper of the operator at the distant station been clearly read at the receiving station, even though situated some hundred miles distant. When the direction of the currents from the two stations are passed into the wire in the same direction, the directive force of the needle becomes more decided, and when the direction is contrary the motion of the needle will be comparatively neutralised and scarcely perceptible. The effect of a current transmitted along a wire from one station upon a galvanometer needle while currents are being transmitted from another station has therefore been long known. How this circumstance has been applied to the indication of distinct signals will now be explained.

Let us suppose two stations, A and B, are to be connected for signalling each other upon the Duplex system: the action of the coils in the instruments at the respective stations is so arranged that neither station's local or outgoing current shall affect its needle when passed into the line, its dial being left free to indicate the effects produced by the incoming current from the distant station. For this purpose it is necessary to wind the coils of the instruments with two parallel wires after the manner of a differential galvanometer. Now, as is well understood in testing a line wire for resistance between two stations with a differential galvanometer, until the artificial resistance interposed has been made equal to that of the line to be tested, the battery current passed by the key into the galvanometer will move the needle in the one direction if the artificial resistance is too small, and in the other direction if the resistance is too great. It is only when an accurate balance is obtained—that is, when the two resistances have been made equal—that a current will not move the needle, because then the current is equally divided between the coil connected with the artificial resistance and that connected to the line, which two coils being wound in opposite directions counteract one another. Thus, so long as the artificial resistances (rheostats) at each end of the line are equal to that of the circuit, each station will see the current sent by the other, while neither station will see upon his own instrument the current he is passing into the line; and for this reason, that the currents sent by each station divide equally between the line and the rheostat, passing through the coils in opposite directions, and have therefore no effect upon the needle of the sending instrument. When the distant station sends a current, it either increases or diminishes the effect of the home current; in the first case, it augments that portion which passes through the coil connected to the line, so that more flows into the line than into the rheostat, and the needle moves. In the second case, it reduces the current flowing to the line, and more will flow through the rheostat, moving the needle in an opposite direction. Thus it is seen that the two currents do not pass one another, but that when both stations signal at the same time, the current sent by either of them acts upon the distant instrument by determining whether the currents sent by that station shall pass through the line or the rheostat. Thus we see that when station A signals separately, the current is equally divided in passing through its instrument coil, and its effect is neutralised upon the needle, but it passes through both coils of the distant instrument in the *same* direction, and therefore produces a signal. If both A and B depress their contact keys at the same moment, the currents from the two batteries are united so far as the line wire is concerned, and this produces an effect upon the differential arrangements at each equivalent to a lessening of the resistance of the line, and therefore more current flows to the line than through the rheostat. It is thus seen that the Duplex system affords a means of increasing the transmitting capacity of a wire; and an invention which practically converts one wire into two, three, or four, as the necessities of business may require, is of great value.

A short historical summary of the introduction and progress of the electric telegraph, from its earliest application in a practical form to the establishment of its present world-wide reputation and utility, will be naturally of interest to the general reader; and the following short sketch may convey in a succinct manner the step by step progress that year by year has registered the index of improvement. It is not intended in any way to make the present sketch personal: some well-known names must of necessity be referred to, and the reader should also

be informed that the narrator in this instance has personally been more or less connected with the progress of the telegraph from 1844, the date at which this story commences, to 1875, the period under review. In the year first mentioned Charles Wheatstone, Professor of Natural Philosophy at King's College, London, was at the same time connected with a musical instrument and publishing business in Conduit Street, Regent Street. In that house many of his important improvements and patents in connection with the electric telegraph were carried out, and many of the drawings connected with the filing of the specifications of those patents were, by permission of the directors of the East and West India Dock Company, elaborated by a clerk in the Dividend Office of the Dock House, Billiter Square; resolutions standing in the Minute Book of the Dock Board authorising the devoting of his spare time in the office to Mr. Wheatstone's telegraph drawings, and afterwards a resignation in favour of an appointment in the then projected Electric Telegraph Company.

Prefaced with these preliminary remarks, the more immediate subject matter of the present paper will be commenced. It is a matter of history that the early telegraph patents of Cooke and Wheatstone were disposed of for a sum of 120,000*l.* to a Company called the Electric Telegraph Company, in which the late John Lewis Ricardo, M.P. for Stoke-upon-Trent, was at once the mainspring and vital element. Of this amount Cooke retained 90,000*l.*, and Wheatstone received 30,000*l.* This sum included the transfer to the Company, besides other matters, of the telegraph line between Paddington and Slough, on the Great Western Railway, already alluded to in the earlier pages of this summary. As already mentioned, this short line was a kind of Madame Tussaud—daily advertisements, and a profusion of visitors entertained, or, as they imagined, duped or bamboozled, at one shilling a head, into the belief that standing before the little instrument in the Paddington station, it would *there* and *then* convey their thoughts, and in intelligible language return a response from a station some twenty miles distant. Inquiries as to the "time of day," "state of weather," or general health of the operator, served to test the accuracy of the new invention. Nevertheless, nine out of every ten persons who were attracted by the printed placards sown broadcast about the station, left the Paddington terminus as little impressed with any belief that what they had seen represented the future germ of a great invention, as if they had viewed the automaton chess player. Necromancy, witchcraft, and delusion seemed to be the parting impression on their minds as they left, in return for their shilling charge. The announcement as issued in 1844, inviting the patronage of the public, is here reprinted; it affords an amusing souvenir of the early history of the telegraph:—

[*Facsimile of Announcement.*]

"Under the Special Patronage
OF ROYALTY.
INSTANTANEOUS COMMUNICATION
between Paddington and Slough, a distance ot nearly twenty miles, by means of the
ELECTRIC TELEGRAPH,
which may be seen in operation Daily, from nine in the morning till eight in the evening at the
GREAT WESTERN RAILWAY, Paddington Station,
and the TELEGRAPH COTTAGE, close to the Slough Station.
Admission—One Shilling, Children and Schools halfprice.

Since this very interesting Exhibition has been opened to the Public, it has been honoured by the visits of His Royal Highness Prince Albert, the Emperor of Russia, the King, and Prince William of Prussia, the Duke de Montpensier, His Royal Highness the Duke of Cambridge, the Duke of Wellington, Sir Robert Peel, the Foreign Ambassadors, and most of the nobility, &c.

"In no way has the science of Electricity been made so subservient to the uses of man, as in its application to the purposes of Telegraphic Communication, which is now brought to the *height of perfection.* The working of this beautiful apparatus is not in the least degree affected by the weather, intelligence can be sent by *night* equally well as by *day*; distance is no object; by its extraordinary agency communications can be transmitted to a *thousand miles* in the same space of time, and with the same ease and unerring certainty, as a signal can be sent from London to Slough. According to the best authorities, the electric fluid travels at the rate of 280,000 *miles in a second*.

"The Electric Telegraph has been adopted by Her Majesty's Government, and the Patentees have just completed a line of communication between London and Portsmouth, agreeably to directions received a short time ago from

THE RIGHT HONORABLE THE LORDS OF THE ADMIRALTY.

"In the late trial of John Tawell, at Aylesbury, for the murder at Salt Hill, near Slough, the Electric Telegraph is frequently mentioned in the evidence, and referred to by Mr. Baron Parke in his summing up. The *Times* newspaper very justly observes 'that had it not been for the efficient aid of the Electric Telegraph, both at the Paddington and Slough stations, the greatest difficulty, as well as delay, would have been occasioned in the apprehension of the prisoner.' Although the train in which Tawell came to town was within a very short distance of the Paddington Station before any intelligence was given at the Slough Telegraph Office, nevertheless, before the train had actually arrived, not only had a full description of his person and dress been received, but the particular carriage and compartment in which he rode were accurately described, and an officer was in readiness to watch his movements. His subsequent apprehension is so well known, that any further reference to the subject is unnecessary.

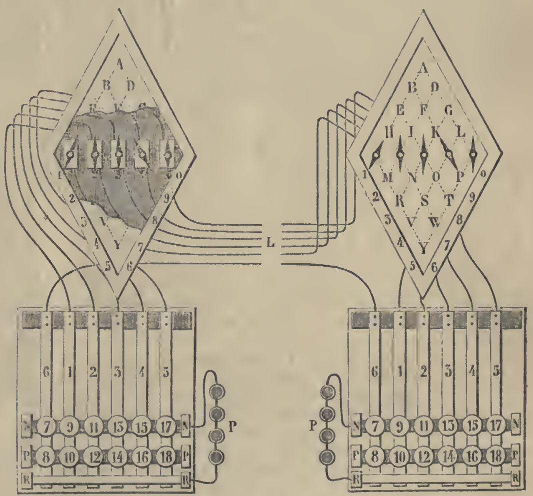

FIG. 26.—Cooke and Wheatstone's five-needle telegraph.]

"The Telegraph Office at Paddington Station is at the end of the Up-train Platform, where a variety of interesting apparatus may be seen in constant operation."

The first office of the Electric Telegraph Company was at 345 Strand, a site now occupied by the Gaiety Theatre. In those days (1846) scientific men of renown crowded the instrument room to witness the progress of this great invention: George Stephenson, the Astronomer Royal, Brunel, Vignoles, G. P. Bidder, Samuda, Rennie, Fairbairn, and most of the leading engineers of the day. In

345, Strand, the magnetic disturbances and interference with transmitted signals from auroræ and earth-currents were first observed and the observations tabulated, which have since proved useful, notwithstanding the then defective construction of the recording apparatus; here also the earliest lines of railway telegraph were inaugurated; the long five-inch astatic combination of the double needle and single needle instruments was employed, taking the place of less perfect apparatus. It must be remembered that, previous to the introduction of the double and single needle instruments, very cumbersome apparatus had been employed. There was the five-needle instrument, requiring five wires for the five needles, and a sixth wire for the return current (Cooke and Wheatstone's patent, 1837);

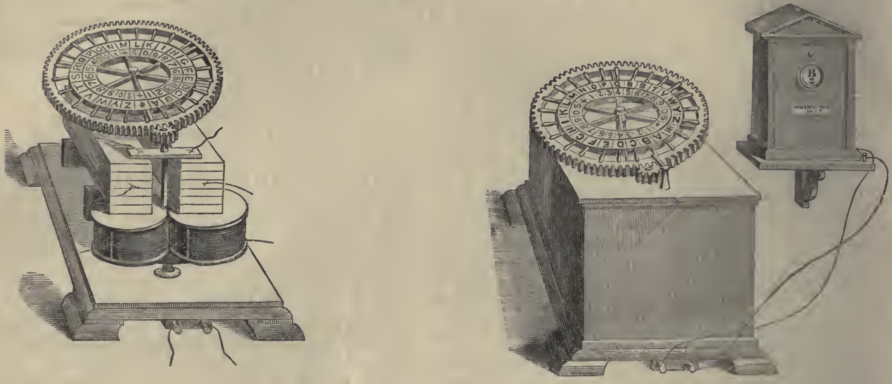

FIG. 27.—Wheatstone's letter-showing dial telegraph, 1840.

the respective letter or signal being indicated by the concurrent deflection of two pointers. Obviously, this instrument became useless for extended circuits, the capital cost of outlay for the six wires restricting its use. The old letter-showing apparatus of Cooke and Wheatstone (1840), in which the letters of the alphabet composing the word are severally presented to view at an opening in a dial-plate by means of an electro-magnet acting upon the pallets of an escapement, put in motion by independent clockwork. The communicator of the instrument is furnished with a dial-plate similar to that of the indicator, so that on the rotation of the dial of the communicator by the operator, the necessary succession of make and break currents of electricity are sent through the wire and controlled so as to actuate the motion of the index-pointer of the indicator at the distant station.

(*To be continued.*)

THE INDIAN TRIGONOMETRICAL SURVEY*

ONE does not usually expect to find much of general interest in the Report of a Trigonometrical Survey. Col. Walker's admirably drawn-up Report, however, includes some matter of more than special value; indeed, many of the details connected with the immediate work of the Survey are calculated to interest the general reader, they are concerned to such a large extent with the peculiar difficulties to be overcome by the various parties, difficulties which make ordinary survey work look like mere child's play.

The Index Chart prefixed to the Report enables one to form a very full idea of the work which has already been done, and of how much there is yet to do. From Cape Comorin to Peshawur and all along the Himalayan frontier, and from Kurrachee on the west to Burmah on the east, the country is covered with an intricate net-work of triangulation, including, however, many gaps which will take many years to fill up. Shooting out from the northern border of the system of triangulation are numerous aurora-like lines indicating the secondary triangulation to fix the peaks of the Himalayan and Sooliman ranges. We cannot go into the details of the work of the Survey, and must content ourselves with a brief summary of the out-turn of work during the year under review, and with a reference to a few of the more interesting side topics.

Of Principal Triangulation, with the great theodolites of the Survey, seventy triangles, embracing an area of 7,190 square miles, and disposed in chains which, if united, would extend over a direct distance of 302 miles, and in connection with which three astronomical azimuths of verification have been measured. Of Secondary Triangulation, with vernier theodolites of various sizes, an area of 5,212 square miles has been closely covered with points for the topographical operations, an area of 3,650 square miles has been operated in *pari passu* with the principal triangulation but exterior thereto, and in an area of 12,000 square miles—in the ranges of mountains to the north of the Assam Valley which are inhabited by independent tribes—a large number of peaks have been fixed, many of which have already been found serviceable in the geographical operations now being carried on with the military expedition against the Dufflas. Of Topographical Surveying, an area of 534 square miles has been completed in British portions of the Himalayas, on the scale of one inch to the mile, an area of 2,366 square miles in Kattywar on the two-inch scale, and areas of 690 and 63 square miles respectively, in Guzerat and in the Dehra Dún, on the scale of four inches to the mile. Of Geographical Exploration much valuable work has been done in Kashgharia and on the Pamir Steppes, in connection with Sir Douglas Forsyth's mission to the Court of the Atalik Ghazi, and several additions to the geography of portions of Great Thibet and of Nepaul have been obtained through the agency of native explorers.

In the course of the operations of the year under review the northern section of the Brahmaputra Meridional Series has been completed, whereby two important circuits of triangulation formed by it with the Assam and East Calcutta Longitudinal Series to the north and south, the Calcutta Meridional and the Eastern Frontier Series to

* General Report of the Operations of the Great Trigonometrical Survey of India, during 1873–74, by Col. J. T. Walker, R.E., F.R.S., Superintendent of the Survey (Dehra Dun; Office of the Superintendent, G. T. Survey, M. J. O'Connor, 1874.)

the west and east, have been closed. The Straits of the Gulf of Manaar have been reconnoitred, with a view to connecting the triangulation of India with that of Ceylon, which has been found to be feasible.

Probably the most important features in the operations of the principal triangulation of the year are the resumption of the chain of triangles in Burmah, and the completion of the Bangalore Meridional Series for the revision of the southern section of the Great Arc.

Referring to the revision of certain important triangulations which were originally executed at the commencement of the present century with very inferior instruments, Colonel Walker expresses his conviction that no portion of the principal triangulation remains which will ever require to be revised, and that the last of the old links in all the great chains of triangles which might with any reason have been objected to as weak and faulty, have now been made strong and put on a par with the best modern triangulation.

The pendulum observations have been completed, and the final results are now being computed and prepared for publication.

Considerable assistance was, moreover, rendered to Col. Tennant in the operations connected with the observation of the Transit of Venus; the Appendix contains Mr. Hennessey's account of his observations at Mussooree, the details of which have already appeared in NATURE.

The reports of the various district superintendents are very full, and contain a good deal that is of general interest; the accompanying district sketch-maps are of great use in enabling one to read these reports with understanding. We shall briefly refer to some of the points of more general interest.

In Major Branfill's report on the Bangalore Meridional Series, a very interesting phenomenon is noticed in connection with the Cape Comorin base-line. The operations of 1873–74 were intended to close in a side of the polygon around the base-line which had been completed in 1868-69; but it was found that one of the two stations on the side of junction had disappeared. This station was situated on a remarkable group of Red Sand Hills, where, in 1808, Col. Lambton had constructed a station by driving long pickets into the drift sand; in 1869 Major Branfill, finding no trace of these pickets, had caused a masonry well to be sunk to a depth of ten feet, where it reached what was believed to be firm soil below; but during the interval of four years this well had been undermined, and nothing remained thereof but some scattered *débris*. It would appear that the sand hills travel progressively in the direction from west-north-west to east-south-east, which is that of the prevailing winds in this locality; if Col. Lambton's station was situated on the highest point of the hills and in a similar position relatively to the general mass as Major Branfill's, then the hills must have travelled a distance of about 1,060 yards to the E.S.E., for the results of the triangulation show that this is the distance between the positions of the two stations; thus the rate of progression would be about seventeen yards per annum. From Major Branfill's Notes on the Tinnevelly district, which are appended to the General Report for 1868-69, it appears that certain measurements of the eastward drift had made it as much as 440 yards in the four years 1845-48; but the distance between the trigonometrical stations of 1808 and 1869 probably affords the most accurate measure which has hitherto been obtained of the rate of progress of this remarkable sand-wave, which gradually overwhelms the villages and fields it meets with in its course, and has never yet been effectually arrested; numerous attempts have been made, by growing grass and creepers and planting trees on the sands, to prevent the onward drift, but they have hitherto been unsuccessful.

Mr. Bond, one of Major Branfill's staff, managed to procure an interview with a couple of the wild folk who live in the hill jungles of the western Ghâts, to the southwest of the Palanei hills. A strange dwarfish people had often been heard of as frequenting the jungles near the station of Pémalei, in the north-west corner of the Tinnevelly district, but until Mr. Bond caught these two specimens no trace of them had been seen by the members of the Survey. These two people, a man and a woman, believed themselves to be 100 years old, but Mr. Bond supposes the man to be about twenty-five, and the woman eighteen years of age. "The man," Mr. Bond states, "is 4 feet 6½ inches in height, 26¼ inches round the chest, and 18½ inches horizontally round the head over the eyebrows. He has a round head, coarse black, woolly hair, and a dark brown skin. The forehead is low and slightly retreating; the lower part of the face projects like the muzzle of a monkey, and the mouth, which is small and oval, with thick lips, protrudes about an inch beyond his nose; he has short bandy legs, a comparatively long body, and arms that extend almost to his knees: the back just above the buttock is concave, making the stern appear to be much protruded. The hands and fingers are dumpy and always contracted, so that they cannot be made to stretch out quite straight and flat; the palms and fingers are covered with thick skin (more particularly so the tips of the fingers), and the nails are small and imperfect; the feet are broad and thick skinned all over; the hairs of his moustache are of a greyish white, scanty and coarse like bristles, and he has no beard.

"The woman is 4 feet 6½ inches in height, 27 inches round the chest (above the breasts), and 19½ horizontally round the head above the brows; the colour of the skin is sallow, or of a nearly yellow tint; the hair is black, long, and straight, and the features well formed. There is no difference between her appearance and that of the common women of that part of the country. She is pleasant to look at, well developed, and modest." Their only dress is a loose cloth, and they eat flesh, but feed chiefly on roots and honey.

"They have no fixed dwelling places, but sleep on any convenient spot, generally between two rocks or in caves near which they happen to be benighted. They make a fire and cook what they have collected during the day, and keep the fire burning all night for warmth and to keep away wild animals. They worship certain local divinities of the forest—Rákas or Rákári, and Pé (after whom the hill is named, Pé-malei)."

The woman cooks for and waits on the man, eating only after he is satisfied.

The means taken for tidal observations in the Gulf of Kutch promise to lead to valuable results. The object of these observations is to ascertain whether secular changes are taking place in the relative level of the land and sea at the head of the gulf. Very great difficulties were found in selecting suitable stations for fixing the tide-gauges, as the foreshores of the gulf consist mainly of long mudbanks, which often stretch miles into the sea, and are left bare at low water, when they are intersected by innumerable tortuous and shallow creeks, whose shifting channels would be very unfavourable positions for tide-gauges. Only three points suitable for tidal stations were met with on the coasts of the gulf: at Hanstal Point, near the head of the gulf; at Nowanár Point, half-way up, on the Northern or Kutch coast; and at Okha Point, on the southern coast, opposite the island of Beyt. None of these points, however, are situated in ports or harbours, where piers, jetties, landing-stages, or docks might have been utilised; on the contrary, they are all situated at some distance from the nearest inhabited localities, and present no facilities whatever. The operations had thus to be of the very simplest nature. The only practicable plan was to have the tide-gauges set up on shore, over wells sunk near the high-water line, and connected with the sea by piping. The wells are iron cylinders, with an internal diameter of twenty-two inches, which slightly

exceeds the diameter of the float; the cylinders were made up in sections of fifty inches in length, the lowest of which is closed below with an iron plate, and the whole, when bolted together, forms a water-tight well, into which water can only enter through the piping for effecting the connection with the sea. The piping is of an internal diameter of two inches, which has been computed to be sufficient to permit of the transmission of the tidal wave to the well without sensible retardation. Iron piping is laid from the well to the line of low water; it is brought vertically up from the bottom of the well nearly to the surface of the ground, and is then carried down to the sea, where flexible gutta-percha piping is attached, and carried into the deep water. The outer piping terminates in a "rose," which is suspended a few feet above the bed of the sea by a buoy, in order to prevent the entrance of silt as much as possible, and it can be readily detached from the iron piping whenever it has to be cleaned.

After many difficulties, and even dangers to life, Capt. Baird's party managed to get the gauges erected and set to work, and what with the tidal observations, observations of the barometric pressure, the velocity and direction of the wind, and the amount of rainfall—for each station has been provided with means for making such observations—very valuable results may be expected.

Lieut. Gibbs's notes on the portion of the Dang Forests, in the Guzerat district, visited by him in 1874, are of great interest, and we regret that space forbids us referring to them in detail. His observations on the inhabitants of this region are of special value; he also seems to have paid considerable attention to the fauna, flora, and geology of the district.

Capt. Heaviside's lively narrative of the pendulum work in India, of his journey home, and of the operations at Kew, will also be read with interest.

Two narratives of somewhat unusual interest are given in the Appendix. One of these, by Lieut.-Col. Montgomerie, gives an account of a journey to the Namcho or Tengri Núr Lake, in Great Thibet, about ninety miles north of the Brahmaputra, by a native explorer, during 1871-72. The explorer was a semi-Thibetan, a young man who had been thoroughly trained for the work, and who was accompanied by four assistants. The party set out from Kumaon in November, and crossed the Brahmaputra at Shigatze, and amid considerable hardships made their way northwards, reaching the lake about the end of January, when they found it completely frozen over, although the water is so salt as to be unfit for drinking. The party intended to travel all round the lake, which is 15,200 feet above the sea, fifty miles long and from sixteen to twenty-five miles broad, and intended to proceed further to the northward and take complete surveys, but were robbed of nearly all they had, and were thus compelled to beat a rapid retreat, which they did by way of Lhásá.

During the great part of his journey to the Namcho Lake the explorer found the streams all hard frozen, and he was consequently much struck by the number of hot springs that he met with, and more especially by the great heat of the water coming from them, his thermometer showing it to vary from 130° to 183° Fahrenheit, being generally over 150°, and often within a few degrees of the boiling point, being in one case 183° when the boiling point was 183¾°. The water generally had a sulphurous smell, and in many cases was ejected with great noise and violence; in one place the force was sufficient to throw the water up from forty to sixty feet. These springs in some respects seem to resemble the geysers of Iceland.

To the south the lake is bounded by a splendid range of snowy peaks, flanked with large glaciers, culminating in the magnificent peak "Jáng Ninjinthanglá," which is probably more than 25,000 feet above the sea. The range was traced for nearly 150 miles, running in a northeasterly direction. To the north of the lake the mountains were not, comparatively speaking, high, nor were there any high peaks visible further north as far as the explorer could see from a commanding point which he climbed up to. He only saw a succession of rounded hills with moderately flat ground in between them. Immediately north he saw a lake of about six miles in length, which he was told was called Bul Cho, from the borax (bul) which is produced there in large quantities, supplying both Lhásá and Shigatze with most of the borax that they require.

The Tengri Núr or "Namcho" Lake is considered to be a sacred place, and although at such a very great distance from habitations and so high above the sea, it boasts of several permanent monasteries and is visited by large numbers of pilgrims. There are several islands in the lake, two of them large enough for monasteries: at the time the explorer was there the Lámas on the islands kept up their communication with the shore by means of the ice, but he did not hear as to what was done in summer. Fish are said to be abundant, and modern lake shells were found on the shore as well as fossil shells, which were very numerous and of all sizes.

The narrative contains many other valuable observations made on the people and the country through which he travelled; there is a good map of the route.

The other narrative is quite equal in interest to that just referred to. It consists of extracts from a native explorer's narrative of his journey from Pítorágarh in Kumaon *viâ* Jumla to Tadum, and then down through Nepaul, along the Gandak River, to British territory. The explorer, who had to exercise much determination and ingenuity, took minute notes by the way of all he saw, and has added much to our knowledge of the geography, the people, and the products of a region comparatively unknown. He had to cross many rivers by the way, which was generally done by means of ropes suspended between the banks. The explorer wished to proceed much further than Tadum, which is a little beyond the Brahmaputra, in Great Thibet, but was prevented by the head man of the village. He started on July 1, 1873, and reached British territory again about the end of November, after having travelled nearly 500 miles. We have space to notice only one interesting phenomenon which he observed. At Muktináth, near Kágbeni, about 11,280 feet above the sea, in N. lat. 29° and E. long. 83° 45′, about 600 feet south of the temple, is a small mound with a little still water at its base, having a sulphurous smell. From a crevice in this mound, at the water's edge, rises a flame about a span above the surface. The people of the place told the explorer that the water sometimes increases in quantity sufficiently to flow into the crevice; the flames then disappear for a while, and there is a gurgling noise, a report, and the flames burst up and show again. This spot is called Chume Giarsa by the Bhots.

Our readers will see, from the cursory glance we have been able to take at this Report, that it contains much valuable matter apart from the immediate work of the Survey, the members of which are doing good service to India and to science.

THE BIOLOGICAL DEPARTMENT OF THE BRITISH MUSEUM

THE newly-issued Report of the condition and development of the British Museum has, so far as biologists are concerned, a special interest. Its results may be considered as an index of the public feeling on the importance of the study of Natural History. Looked at in this light, we think that specialists in all the departments may feel hopeful. The acquisitions to the Zoological Department have been numerous (30,699 in all), over 6,000 being Vertebrata, "the majority being either entire

animals preserved in spirits, or skeletons." The spirit collection till recently has been much neglected, and all who have wished to prosecute their investigations into the more intricate details of zoology and comparative anatomy —into points of myology, nerve distribution, &c., quite as important as, but much less easily arrived at than, osteological characters—may justifiably look forward to the time when the national collection will contain, preserved in their entirety, examples of all reasonably-sized species.

"In the acquisition by purchase of skeletons, particular care has been taken [we are told] that they should be those of animals captured in a wild state, the skeletons of mammals (and birds) which have been brought up or have lived for some time in menageries, showing rarely, if ever, a perfect development of the osseous system. Scarcely less caution is required in admitting specimens of this kind into the collection for the sake of their skins." There is a great deal of truth in these remarks, but there are many new species of animals, such as the new Mourning Kangaroo, brought over by M. d'Albertis, and the Hairy-eared Rhinoceros (*Rhinoceros lasiotis*), discovered by Mr. Sclater, and now enjoying perfect health in the Zoological Society's Gardens, which are only known from these individuals.* It would be a loss to the collection if these were not obtained when opportunity afforded, and we are glad to know that the small kangaroo referred to has died and has been secured by Dr. Günther.

We are informed that over three thousand students who have visited the department during the past year, with the object of consulting the various portions of the collections, "have been assisted and attended to." All, we are convinced, will agree in expressing their best thanks to Dr. Albert Günther, who, as the worthy successor of the late Dr. J. E. Gray, has done all in his power to place every facility in the way of those who are desirous of studying Natural History.

* A second specimen of the latter species has been just received by Mr. C. Jamrach.

NOTES

M. Leverrier was expected in England during the present month; but as the revision of his planetary theories, and especially of the Theory of Saturn, in which he has been occupied for some time, is not yet completed, his visit to this country will be delayed.

The Emperor of Brazil has sent to Prof. Virchow, accompanied by an autograph letter in French, an interesting collection of skulls and skeletons, amongst which are some found in ancient caverns of Brazil. The collection has been made at the Emperor's request by the director of the Museum at Rio, Señor Ladislas Neto. The Emperor regrets that he did not have the pleasure of making Prof. Virchow's acquaintance at Berlin when he visited that city, as the Professor's investigations "are highly esteemed even by those to whom, like myself, it is not given to be more than friends to science."

The Geographical Society of Rome gave a banquet, on May 11, to the celebrated African traveller Dr. Nachtigal; many of the members and several notabilities of the city of Rome were present in honour of the guest. The Vice-president of the Society, Senator Amari, proposed the health of the guest, who had just returned from a journey through Fezzan, Bornu, Wadai, and Darfur. Dr. Nachtigal, in reply, wished success to the scientific expedition to Central Africa planned by the Society; he considered that this expedition would be an honour to the whole Italian kingdom.

The transfer of the India Museum to the Eastern Galleries of the International Exhibition Buildings, South Kensington, having been completed, the collection was thrown open to the Institute of Civil Engineers, who had a brilliant *conversazione* in the galleries on Tuesday evening; there were about 2,500 present. Considerable advance has been made in the arrangement of the valuable collections belonging to the Museum, though it must necessarily take some time before everything can find its proper place. There are two galleries, the upper and the lower. In the former, the Manufactures and Arts of India are represented; in the latter, which are not yet finished, the Natural History of Hindostan, the mineral, vegetable, and animal products, are represented. No doubt the India Museum, as it will ultimately be arranged, will become a favourite and instructive resort of the public, and we hope it is only the first step towards the realisation of Dr. Forbes Watson's great scheme of an Indian Institute.

Mr. H. H. Sclater, the naturalist to the Rodrigues section of the late Transit of Venus Expedition, and the Rev. A. E. Eaton, who held the same position at Kerguelen's Land, are both working out the materials which they collected during their stay in the islands which they visited. The former zoologist has obtained a great number of remains of the extinct Solitaire, one skeleton and several skulls being perfect; besides the remains of several other species of birds. Mr. Eaton's specimens include the skeleton of one Cetacean, two Seals, and several species of Petrels.

Dr. Lyon Playfair has withdrawn his bill for restricting experiments on animals, on account of the appointment of a Royal Commission on the subject, the names of the members of which have not yet been published.

Prof. Leidy, the distinguished American biologist, is now in this country.

The volcanic phenomena in Iceland, of which we have already given some details (vol. xi. p. 514) seem still to be as active as ever, and indeed to be gaining in intensity. Outbreaks have occurred since the beginning of the year to the middle of April, when the latest news left. In March the Dyngjufjöll was incessantly vomiting fire, the eruption was steadily spreading over the wilderness, and the whole region of the My-vatn Mountains was one blazing fire. So large a district of the surrounding country has been covered with ashes that the farmers have been obliged to remove in order to find pasture for their stock. Early in April a new eruption had broken out in a south-easterly direction from Barfell, more than half-way to the east, between it and the Jokulsa. A party went out from Laxárdal to explore, and on approaching the place of eruption they found the fire rising up from three lava craters, in a line from south to north, which it had piled up around itself on a perfectly level piece of ground. At a distance of fifty to eighty fathoms to the west from the craters a large fissure had formed itself as the fire broke out, and the land had sunk in to the depth of about three fathoms. Into the hollow thus formed the lava had poured at first, but now it flowed in a south-westerly direction from the two southern craters. The northernmost crater had the appearance of being oblong, about 300 fathoms in length, and from this crater the molten red-hot lava was thrown about 200 or 300 feet into the air in one compact column. The top of this column then assumed a palmated appearance, and the lava fell down in small particles, like drops from a jet of water, which, as they became separated from the column, grew gradually darker, and split into many pieces, bursting into lesser and lesser fragments as they cooled. No flames were observed, but the glare proceeds from these columns and the seething lava in the craters. At times the explorers could count twenty to thirty of these columns. No real smoke accompanied the eruption, but a bluish steam, which expanded and whitened in colour as it rose to a greater distance from the crater, and such seemed to be the power of this blue jet of steam that it rose straight into the air for many hundreds of fathoms in despite of a heavy wind blowing.

A SHOCK of earthquake was felt at Spezzia, Italy, on May 20. It is possible that the earthquakes which were felt almost daily in Italy a few weeks since were connected with the Icelandic phenomena; generally, any volcanic commotion in Iceland occurs simultaneously with volcanic or seismic phenomena in Italy.

THE University of Cambridge proposes to confer the honorary degree of LL.D. upon Dr. Samuel Birch, F.S.A., the Keeper of Oriental Antiquities in the British Museum.

THE death is announced, on Feb. 5 last, at the age of thirty-five years, in the interior of Africa, of Mr. Frank Oates, F.R.G.S., who, since the beginning of 1873, has been travelling in that country with the twofold object of acquiring an accurate knowledge of its natural features and of studying its fauna. After spending some time in the Matabele country, north of the Limpopo River, towards the end of last year Mr. Oates proceeded to the Victoria Falls, on the Zambesi. Shortly after leaving the Zambesi, when near to the Makalake towns, he succumbed to fever. Mr. Oates's effects, it is hoped, will be brought home by a personal friend, who has recently gone up country from Pietermaritzburg. They include a large number of specimens of natural history and curiosities which Mr. Oates had collected, besides all his notes and papers, and are expected to prove of very considerable interest. Mr. Oates had already made a successful expedition into North and Central America.

THE Report read at the Anniversary of the Royal Geographical Society on Monday shows a net increase of 202 members, the roll of ordinary members now reaching the total of 2,960. The total income of the year was 7,511*l.* 11*s.* 10*d.*, all but about 500*l.* of which has been disbursed. Medals were presented to Count von Beust on behalf of Lieuts. Weyprecht and Payer, and to the successful competitors in the public schools examinations. A presentation gold watch was handed by the chairman, Sir H. C. Rawlinson, to Col. Montgomerie, of the Indian Trigonometrical Survey, for transmission to Mr. W. H. Johnson, the explorer of Kuen Lun and Khotan. The President, in his address, referred to the losses by death sustained by the Society, to the Arctic Expedition, to the Admiralty Surveys in the *Challenger*, the *Basilisk*, the *Shearwater*, and other vessels, and to other geographical topics.

MR. WILLIAM MACLEAY, of Sydney, who has fitted out the expedition for the exploration of New Guinea, is, we believe, an ardent naturalist. The ship he has purchased is named the *Chevert*, and has been placed under the command of Captain Edwards. Mr. Macleay accompanies the expedition, which left Sydney on the 18th inst.

THE body of an American, John Blackford by name, has recently been found in a large ice-block in the vicinity of Mont Blanc, after several days of thaw. The unfortunate tourist had tried three years ago to ascend Mont Blanc without a guide, and had not since been heard of. Features and clothes are perfectly preserved.

IN the vicinity of Salzwedel an immense layer of rock-salt has been discovered. Borings had been made for some time past with a view to discovering coal; the formation of limestone, however, in which these experiments were made, is extremely hard, and the borings made but small progress. At the beginning of this year the first specimens of rock-salt were obtained at a depth of about 730 feet. The borings have now gone 250 feet deeper, and the rock-salt remains the same. It is the intention of the proprietor to go to a depth of 2,000 feet.

MR. MALLET's paper on "The Nature and Origin of Volcanic Heat and Energy," read to the Royal Society in 1872, and published in Phil. Trans. for 1873, has been translated in full into German by Dr. A. von Lasaulx, Professor of Geology at the University of Bonn, and published as a separate work. We regret that a few clerical errors which escaped correction until the original paper was published, together with the necessary errata, have been overlooked by the translator. The errors are, however, self-evident, and occur in the German translation in paragraphs 186 to 198. The errors originate by dividing, in place of multiplying, a certain number of heat units at line 11, par. 186, and do not affect the argument of the paper.

A LITTLE medal of palladium, with hydrogen occluded in it, now at Leeds, is described by the compiler of the "Yorkshire Exhibition Guide" in the following terms:—"A medal and plate formed of the new metal, palladium, will be interesting to scientific men. The discovery of this metal by Prof. Graham a few years ago finally settled the long-disputed point as to whether or not the gas hydrogen was a metal. He proved that palladium was simply hydrogen condensed. This may be easily exemplified by placing a piece of the metal under the receiver of an air-pump and exhausting the air. The solid metal at once flies off as a gas, and on re-admitting the air it shrinks again into its former size. The little medal shown contains 100 times its volume of the gas." The writer's wild remarks display so much ignorance, that it is to be feared, notwithstanding their calm positiveness, they can hardly be attributed to a firm and cheerful faith in molecular mobility.

THE French Academy of Sciences, at its private meetings, is at present deliberating upon the means of diminishing the expenses of publishing the *Comptes Rendus* without injuring the interest of science. The yearly expense of editing that journal is about 70,000 francs, after deducting the receipts from the sale, which is not very large. The Academy has a very liberal free list, the number of copies presented amounting to many hundreds. It has been proposed by M. Leverrier to use a smaller type. Objections have been raised by some members, who wish merely to diminish the number of pages allotted to the several papers. But it is very likely that the former suggestion will be adopted, and steps taken to make the *Comptes Rendus* less bulky. The *Comptes Rendus* forms yearly two thick quarto volumes. The eightieth volume is in course of publication. The number of pages published since the 1st of June, 1835, is about 100,000.

THE Report of Brigadier-General Myer, Chief Signal Officer of the United States for 1874, has just been received. This Report, giving an admirable *résumé* of the meteorology of the United States for 1873–74, and exhibiting throughout an earnestness and a vigour in the successful application of the science to practical matters, we shall take an early opportunity to bring before our readers.

SYMONS' "British Rainfall," showing the distribution of rain over the British Isles during 1874, as observed at about 1,700 stations, has just been published. It contains, in addition to the usual large mass of valuable information detailing the rainfall of the year, a notice of the remarkable rainfall of October 6, and a map showing its distribution over England and south of Scotland; and papers on the measurement of snow and on the rainfall at certain health-resorts in the United Kingdom. We observe with much satisfaction that the editor has obtained the services of nine gentlemen as county superintendents, to assist him in collecting the rain returns of their respective districts, it being in this way that the observation of this important element will best be rendered still more complete. The publication of the monthly as well as the annual amounts of rain for the whole of the 1,700 stations is very desirable, and it is hoped that in an early issue of the "British Rainfall" it will be done.

A NEW street in Magdeburg has just been called "Guerike Street." Our readers know that Otto von Guerike, some time Burgomaster of Magdeburg, was the inventor of the air-pump.

ON May 20 the Plenipotentiaries of France, Austria, Germany, Italy, Russia, Spain, Portugal, Turkey, Switzerland, Belgium,

Sweden, Denmark, the United States, the Argentine Republic, Peru, and Brazil, signed, at Paris, the International Convention for the adoption of the metrical system of weights and measures. A special clause reserves to the States not included in the above list the right of eventually adhering to the Convention.

IT was the Hon. T. Elder (not Eden), who, with Mr. Hughes, bore the expenses of Col. Warburton's journey across Australia, the narrative of which we noticed in last week's NATURE (p. 46).

THE French Association for the Advancement of Science meets at Nantes this year, under the presidency of M. d'Eichtal, an influential banker largely connected with railway interests. The local committee is presided over by the Mayor, and a large sum has been collected for defraying the expenses connected with the meeting.

THE annual report of the trustees of the Museum of Comparative Zoology, of Cambridge, U.S., for 1874 has just been published, and contains the current history of that distinguished establishment, as also the list of the additions to its various departments. The strict economy necessary to relieve the Museum from its embarrassments, after the death of Prof. Agassiz, has effected its purpose, and its financial condition is rapidly approaching a satisfactory state.

PROF. ALEXANDER AGASSIZ announces that the experience of the past two years has shown the impossibility of conducting the Anderson School of Natural History, Penikese Island, upon the plan originally intended. The trustees find themselves at the end of the means at their disposal. To enable them to carry on the school it is proposed to charge a fee of fifty dollars for the season, and they hope that a sufficient number of pupils can be secured to warrant them in going on. Even with the proposed charges there will be a considerable deficit (as was the case last year) to be met by the friends of the Penikese School.

WE believe that M. Wallon, the French Minister of Public Instruction, is to present a law for the organisation of the higher education in France.

THE *Watford Observer* of May 22 contains reports of two papers read at the last meeting of the Watford Natural History Society: "Introductory Remarks on the Observation of Periodical Natural Phenomena," by Mr. J. Hopkinson, F.L.S., and "Notes on the Observation of Plants," by the Rev. Dr. W. M. Hind. It is gratifying to see local societies turning their attention to subjects of so much importance.

DURING the first three days of last week the Geologists' Association made an interesting excursion to Charnwood Forest, in Leicestershire. A full report of the proceedings appears in the *Leicester Chronicle* for May 22.

MESSRS. CHAPMAN AND HALL have just published a translation of F. Jagor's "Travels in the Philippines," of the German edition of which we were able to give a favourable review in vol. viii. p. 138. The translation seems to us to be well done, and the book contains a good map and many illustrations; it merits a favourable reception from the English reading public.

WE have an evidence of the activity of research in the United States in the following list of American Microscopical Societies furnished by the *American Naturalist*:—Agassiz Institute, Sacramento, California; Academy of Natural Sciences, Philadelphia, Biological and Microscopical Section; American Association for the Advancement of Science, Microscopical Section; American Microscopical Society of New York; Bailey Club, New York; Boston Microscopical Society; Boston Society of Natural History, Microscopical Section; Dartmouth Microscopical Club, Hanover, N. H.; Fairmount Microscopical Society of Philadelphia; Indiana Microscopical Society, Indianopolis, Ind.; Kirtland Society of Natural History, Cleveland, Ohio, Microscopical Branch; Louisville Microscopical Society, Louisville, Kentucky; Maryland Academy of Sciences, Baltimore, Section of Biology and Microscopy; Memphis Microscopical Society, Memphis, Tenn.; New Jersey Microscopical Society of the City of New Brunswick, N. J.; Providence Franklin Society, Providence, N. J., Microscopical Department; San Francisco Microscopical Society; Society of Natural Sciences, Buffalo, N.Y., Microscopical Section; State Microscopical Society of Illinois, Chicago, Ill.; State Microscopical Society of Michigan, Kalamazoo, Mich.; Troy Scientific Association, Troy, N.Y., Microscopical Section; Tyndall Association, Columbus, Ohio, Microscopical Section. Eight of these societies have been established within the last two years.

WE have received the Eighth Annual Report of the Perthshire Society of Natural Science, from which we regret to see that there has been rather a falling-off in the prosperity of the Society, arising mainly from indifference on the part of the majority of its members. In this, as in most other similar societies, the work is done by but a small portion of the members. Still the Society is working well in various ways, and this report contains a long and interesting address by the President, Sir Thomas Moncrieff, on the work done by the Society during the past year. We hope the publication of this Report will be the means of rousing a larger number of the members to take an interest in the work of the Society.

THE Report for 1874, read at the thirteenth annual meeting of the West Riding Consolidated Naturalists' Society, embracing a large number of Field Clubs in the West Riding, is a very favourable one. At the time of the meeting, some months ago, the number of members was 545, and the Report states there is good reason to believe that studies in the various branches of Natural History are now diligently and earnestly pursued.

THE additions to the Zoological Society's Gardens during the past week include a Black Ape (*Cynopithecus niger*) from Celebes, presented by the Hon. Evelyn H. Ellis; a West Indian Agouti (*Dasyprocta antillensis*) from Trinidad, presented by Mr. Christopher James; a Coypu Rat (*Myopotamus coypu*) from South America, presented by Mr. Robert E. Paton; a King Penguin (*Aptenodytes pennanti*) from the Falkland Isles, presented by Mr. L. Cobb; an Indian Cobra (*Naia tripudians*), two Russell's Vipers (*Vipera russelli*), three Carpet Vipers (*Echis carinata*), an Indian Eryx (*Eryx johnii*), an Indian Python (*Python molurus*), three Indian Rat Snakes (*Ptyas mucosa*), and five Long-snouted Snakes (*Passerita mycterizans*), from India, presented by Dr. John Shortt; two Rendall's Guinea Fowls (*Numida rendalli*) from West Africa, two King Parrakets (*Aprosmictus scapulatus*) from New South Wales, deposited; a Molucca Deer (*Cervus moluccensis*), born in the Gardens.

SCIENTIFIC SERIALS

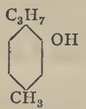
Journal of the Franklin Institute, April.—The following are the principal original papers in this number:—Report on a test trial of a Swain turbine water wheel, by J. B. Francis, C.E.—On the moments and reactions of continuous girders, by M. Merriman, C.E.—Compound and non-compound engines, steam jackets, &c., by C. E. Emery, C.E.; this is the first part of a paper presenting a discussion of the results of experiments made on several U.S. Government steamers.—First part of a paper on experiments made at the Mare Island Navy Yard, California, with different screws applied to a steam launch, to ascertain their relative propelling power, by Chief Engineer B. F. Isherwood, U.S.N.—New processes in proximate gas-analyses, by Prof. Henry Wurtz, continued from a former number.—On the cause of the light of flames, being a translation from the German of W. Stein, who discusses the results attained by Prof. Frankland.

Der Naturforscher, Feb. 1875.—This valuable publication contains abstracts of many important papers published elsewhere, most of which are noticed separately in NATURE; but there are also numerous original papers. We point out the following:—On the elements of the flora of the Chalk period, by C. v. Ettingshausen.—On the nature of lichens, by P. Magnus. This is an account of the difference of opinion existing amongst the authorities on the subject in question, some of whom do not think lichens uniform organisms, but rather suppose them to consist of a fungus which draws the greatest part of its organic substance from the Algæ (the so-called lichen Gonidia) round which it grows, while others do not agree with this view; the author, however, tends to the adoption of the idea as a correct one.—On the Biela Comet shooting stars observed by Herr Winnecke at Strasburg on Dec. 3 last.—On the revival of Rotifera, by Mr. Leidy.—On the atmospheric peroxide of hydrogen, by Herr Houzeau.—On the colour and specific gravity of sea-water; observations made on board the German Expedition corvette *Gazelle* on her voyage to the Kerguelen Island, under the superintendence of Herr von Schleinitz. These observations seem to show that the blue colour of sea-water stands in close relation with the quantity of salt the water contains, and that as the salt decreases the colour passes from blue to blue-green and dark green. There seems to be such regularity in this, that simply according to the specific gravity of the water the shade of colour could be determined which the water must show, and *vice versâ*. The transparency of the water seems also to increase with its quantity of salt; that of blue water was found to be 4·7 meters, while that of dark green only 2·5 meters.—On the nature and the laws of adhesion, by J. Stefan.—On the assimilation of nitric and sulphuric acids by germinating peas, by Herr Kellner.—New researches on some absorption phenomena of field-soils, by Herr Eichhorn.—On the spectra of comets, by H. C. Vogel, with special reference to Coggia's Comet.—On the copulation of spores of Algæ, by P. Magnus.—On the digestion of albumen, by R. Maly.—On a new method to investigate the nature of electric discharges, by Herr A. M. Meyer.—On a new theory of the sensation of light, by Herr E. Hering. This theory refutes that of Young and Helmholtz, which adopts three simple colours, red, green, and violet, and sometimes requires certain psychic processes for explaining certain facts. Herr Hering tries to do away with these processes in question.—On the new malleable glass, by Herr J. Fahdt.—On the decomposition of preserved wood, by Max Paulet.

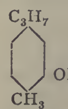
Zeitschrift der Oesterreichischen Gesellschaft für Meteorologie, Feb. 15.—This number contains an article on the universal meteorograph, by Prof. Van Rysselberghe, of Ostend. The instrument was fully explained by the inventor at a recent meeting of the Meteorological Society.

March 1.—The subject of rain and the barometric minimum is here further discussed by Prof. Reye, who finds that his views agree in the main with those of Herr Hann. Both these meteorologists recognise the latent heat of vapour as moving force in rotating storms; this causes the air to ascend and fresh air to be drawn in. According to Herr Hann, the barometer only sinks fast after a large whirl with a strong ascending current has been formed. Prof. Reye agrees with him in thinking that the rotatory movement contributes to rarefaction in the centre and thus renders possible the occasional long duration of minima. But he differs with him regarding another point. He considers that the ascending central current can only last so long as its temperature, derived from condensation, exceeds that of the surrounding air, and that this higher temperature must make pressure lower beneath the ascending current than around the cyclone. Dr. Hann, on the contrary, affirms that condensation has little effect on pressure, and that the minima of storm-centres are not caused by rainfall. Mohn's theory of the propagation of storms in the direction of largest rainfall cannot hold good if the latter view be correct. Loomis has shown how American storms generally move towards the area of greatest rainfall. Mohn finds from observations of 210 European stations that moisture is most prevalent on the front side of depressions. Thom testifies to the enormous rainfall accompanying storms in the Indian Ocean. Prof. Reye calculates that if it were possible for rain to fall to the amount of 1 mm. at any place without producing any indraught of air, the barometer would fall $\frac{5}{8}$ of a millimetre, and generally in that proportion. Now, in hurricanes, such a condition is more nearly approached than in thunderstorms or steady rains. In the vortex, air and vapour rise so rapidly that they cannot part with much heat, and at the same time the inflow of the lower strata is retarded and the outflow of the upper strata accelerated by centrifugal force. There still remains, after liberated latent heat has been employed in expansion, a portion which has been disregarded, equivalent to the *vis viva* of the whirling mass and the work of expansion performed in ascending. With all this evidence he maintains his theory.—In the *Kleinere Mittheilungen* we have the last part of Dr. Ucke's paper on atmospheric oxygen, containing tables which give its variations in quantity at different seasons, with reference to the means of all stations together, and of the stations taken separately. At Seringapatam the difference between summer and winter is least, viz., 1 per cent.; London shows 4, Brussels 6, Vienna 8, Petersburg 9, Samara 14, and Barnaoul 16 per cent. Proximity of the sea and elevation obviously produce the low figures, and the more easterly a place lies on the continent the greater are the differences between the seasons.

THE *Gazzetta Chimica Italiana*, fasc i. e ii. 1875, contains the following original papers, besides a great number of abstracts from other serials:—On two new derivatives of phloretic acid, by W. Koerner and P. Corbetta. These are researches on methyl- and ethyl-phloretic acids and their products of oxidation. The authors arrived at the conclusion that phloretic acid can most probably be regarded as phenolisopropionic acid of the formula $C_6H_4 . OH . CH \left\{ \begin{matrix} CH_3 \\ COOH \end{matrix} \right.$.—On the origin of the sulphides and hyposulphides found in natural sulphur waters, by Prof. E. Pollacci.—Researches on some derivatives from natural and artificial thymol, by E. Paterno. The author considers acetylic, methylic, ethylenic, and the sulpho-methylic derivatives of both thymols, and points out their differences.—On paratoluic nitride and some of its derivatives, by E. Paterno and E. Spica.—A note from Dr. M. Fileti, on a glucosate of copper.—Account of experiments made by the same author and E. Paterno, to obtain a carbo-cymenic acid. The experiments made until now with natural thymol and its artificial substitute obtained from cymene, show that both are hydroxyl derivatives of the same cymene, which upon oxidation gives paratoluic acid, and therefore contains the propyl and methyl group in the positions 1 to 4; the difference rests therefore only in the position of the hydroxyl, and as only the two following oxy-derivatives of parapropylmethylbenzine



and



were possible, it remained to be decided which of the two formulæ applied to natural and which to artificial thymol. The nature of the cresols obtained by Engelhardt and Latschinoff, and by Kekulé, by the action of phosphoric anhydride on the isomeric thymols, has rendered it very probable that the first of the above formulæ represents the natural thymol, the other the artificial one. The authors made the experiments of converting sulpho-cymenic acid into carbo-cymenic acid, which has the following formula, $C_6H_3 \left\{ \begin{matrix} C_3H_7 \\ CH_3 \\ COOH \end{matrix} \right.$, and then tried to oxidise the latter, by which they would have finally solved the above question. They have not quite succeeded yet, although they hope to publish their final results shortly.—On the supposed emission of carbonic acid from the roots of plants, by M. Mercadante and E. Colosi. The authors pretend that no such emission exists.—The remainder of the number consists entirely of summaries from other journals, most of which we have already noticed.

IN the 2e fascicule of the *Bulletin de la Société d'Anthropologie de Paris* for 1874, M. Dareste concludes his reply to M. Broca's theory of the mode of formation of double monsters, considering them under the several types named by Isidore G. Saint-Hilaire, "janiceps, iniopes, synotes," and "deradelphes." In a later meeting of the Society, M. Broca entered at great length on the consideration of the "Doctrines of Diplogenesis," and endeavoured to show the untenability of the hypothesis which ascribes this abnormality to fusion rather than to excess of development, and an inherent tendency in the embryo to a repetition or doubling of parts.—A letter was read from M. Prunières, in which he describes the artificial perforations discovered by him in human skulls belonging to the period of dolmens. As early as 1868 the writer first drew attention to the numerous cases in which cranial and other human bones had

been found bearing evidence of having been cut or perforated by instruments belonging to the polished stone age. M. Broca, in describing the crania submitted to his notice by M. Prunières, draws attention to a similar condition in a skull sent to him by Mr. Squier, and taken by the latter from an ancient Peruvian tomb, in which a square opening had been made, evidently by a saw, and probably a few days before death; and he mentions that among the Kabyles and other African tribes trepanning is resorted to in the present day for comparatively unimportant diseases, while Hippocrates refers to the process as one established in his time among the Greeks. M. Broca does not, however, assume that cranial perforations among primitive races in Europe had any connection with surgical processes, but is rather disposed to assume them to have been the result of certain obligations of religion.—M. J. de Baye describes circumstantially the caverns and recesses, amounting to more than one hundred, which he has recently discovered and explored in the Valley de Petit-Morin, in Marne.—M. Bertrand has presented the Society with a cast of a reindeer horn, on which is distinctly traced with a flint instrument the figure of a reindeer grazing, which was found at Thaïnghen, near Lake Constance.—MM. de Quatrefages and Hamy, in offering their colleagues the second edition of their great work on "Crania Ethica," which is entirely devoted to the consideration of the Cro-Magnon race, entered into an exposition of their views in regard to the relations existing between the Troglodytes of Perigord and certain southern races, including not only the Basques, but Kabyle tribes from the Beni-Menasser and Djurjura regions.

SOCIETIES AND ACADEMIES

London

Mathematical Society, May 13.—Prof. Cayley, F.R.S., vice-president, in the chair.—The Rev. C. Taylor read a paper on some constructions for transforming curves and surfaces. The basis of the paper was a neglected work on conic sections, "which for originality and thoroughness is in its own special department unsurpassed." The author was G. Walker, F.R.S., of Nottingham, and his work appeared in 1794. The tediousness of the style may account for the fact that the work was not appreciated. Dr. Hirst and the Chairman made some remarks on the paper.—Mr. J. W. L. Glaisher communicated some notes on Laplace's coefficients.—A short paper by Mr. Harry Hart, on a linkwork for describing sphero-conics and sphero-quartics, was taken as read.

Chemical Society, May 20.—Prof. Abel, F.R.S., president, in the chair.—Mr. A. H. Smee read some notes on milk in health and disease. From the results of numerous experiments he finds that when cows are fed on sewage grass alone the milk soon goes putrid, and the butter made from it is soft, and rapidly becomes rancid. He also noticed the outbreaks of typhoid which had occurred in various places owing to sewage water having been used to cleanse the dairy utensils or to reduce the quality of rich milk to the lowest standard permitted by law. A long and interesting discussion followed, after which Mr. W. H. Deering read a paper on some points in the examination of waters by the ammonia method, in which he proposes certain modifications to facilitate the application of the Nessler test and eliminate incidental errors. There was also a communication from Prof. H. Howe on some Nova Scotian Triassic Trap minerals.

Geological Society, May 12.—John Evans, V.P.R.S., president, in the chair.—The following communications were read.—Notes on the occurrence of *Eozoon canadense* at Côte St. Pierre, by Principal Dawson, F.R.S. The author commenced by describing the arrangement and nature of the deposits containing *Eozoon* at the original locality of Côte St. Pierre on the Ottawa River. The Eozoal limestone is a thick band between the two great belts of gneiss which here form the upper beds of the Lower Laurentian. *Eozoon* is abundant only in one bed about four feet thick; but occasional specimens and fragments occur throughout the band. The limestone contains bands and concretions of serpentine, and is traversed by veins of chrysolite; the former an original part of the deposit, the latter evidently of subsequent formation. A thin section, 5½ inches in depth, showed: (1) Limestone with crystals of dolomite and fragments of *Eozoon*; (2) Fine-grained limestone, with granules of serpentine, casts of chamberlets of *Eozoon* and of small Foraminifera; (3) Limestone with dolomite, and containing a thin layer of serpentine; (4) Limestone and dolomite with grains of serpentine and fragments of supplemental skeleton of *Eozoon*; (5) Crystallised dolomite, with a few fragments of *Eozoon* in the state of calcite; (6) Limestone containing serpentine, as No. 2. The author criticised some of the figures and statements put forward by Messrs. King and Rowney, and noticed two forms of *Eozoon*, which he proposed to regard as varieties, under the names of *minor* and *acervulina*. He stated that fragments of *Eozoon*, included in dolomitic limestones, have their canals filled with transparent dolomite, and sometimes in part with calcite. In one specimen a portion was entirely replaced by serpentine. The author called particular attention to the occurrence of serpentinous casts of chamberlets, single or arranged in groups, which resemble in form those of the Globigerine Foraminifera. These may belong either to separate organisms or to the acervuline layer of the *Eozoon*; the author proposes to call them *Archæospherinæ*, and describes them as having the form and mode of aggregation of *Globigerina*, with the proper wall of *Eozoon*. The author discussed the extant theories as to the nature of *Eozoon*, and maintained that only that of the infiltration of the cavities of Foraminiferal structure with serpentine is admissible. He particularly referred to the resemblance of weathered masses of *Eozoon* to Stromatoporoid corals.—Remarks upon Mr. Mallet's theory of volcanic energy, by the Rev. O. Fisher, F.G.S. Mr. Mallet's paper, read before the Royal Society in 1872, was discussed by the author *seriatim* as far as it seemed open to criticism. With respect to the condition of the earth's interior, whether it be rigid or not, Sir W. Thomson's arguments for rigidity were referred to, and geological difficulties in accepting his conclusions suggested. Mr. Mallet's views regarding the formation of oceanic and continental areas, that they have on the whole occupied nearly the same positions on the globe at all periods from the very first, were objected to on the ground that all continental areas with which we are acquainted are formed of water-deposited rocks, and that therefore those areas must at some time have been sea-bottoms; and if these wide features have not occupied the same positions which they now do from the very first, Mr. Mallet's explanation fails, that they were caused by unequal contraction when the crust was first permanently formed and thin. It was also shown that the theory of unequal *radial* contraction cannot account for the difference of elevation between continental and oceanic areas upon reasonable assumptions. For if we consider the crust to have been 400 miles thick (which cannot be considered *thin*), and to have cooled from 4000° F. to zero (a most extravagant supposition), then, if the crust had contracted one-tenth more beneath the oceanic area than it had done beneath the continental, we should only get a depression of one mile for the oceanic area, using Mr. Mallet's mean coefficient of contraction. The main feature of Mr. Mallet's theory was then discussed, viz., that "the heat, from which terrestrial volcanic energy is at present derived, is produced locally within the solid shell of our globe, by transformation of the mechanical work of compression or crushing of portions of that shell, which compressions and crushings are themselves produced by the more rapid contraction by cooling of the hotter material of the nucleus beneath that shell, and the consequent more or less free descent of the shell by gravitation, the vertical work of which is resolved into tangential pressures and motion within the shell." Mr. Mallet's mode of estimating the amount of heat derivable from crushing a cubic foot of rock was explained, and it was accepted as a postulate, that the heat developed by crushing one cubic foot of rock would be sufficient to fuse 0·108 of a cubic foot of rock; or, in other words, that it would require nearly the heat developable by crushing ten volumes to fuse one. Mr. Mallet considers that the heat so developed may be localised. But Mr. Fisher inquires why, since the work is distributed equally with the crushing, the heat should not be so also; and, since no cause can be assigned why one portion of the crushed portion of rock should be heated more than the rest, assumes that all which is crushed must be heated equally. In short, he is of opinion that if Mr. Mallet's theory were true, the cubes experimented upon ought to have been themselves fused. After paying a just tribute of admiration to Mr. Mallet's elaborate and highly important experiments upon the fusion and subsequent contraction of slags, the author remarked upon Mr. Mallet's estimate of the probable contraction from cooling of the earth's dimensions, showing that it had been based on untenable assumptions. (The author of the paper, however, holds that the contraction of the dimensions of the globe has been greater than *mere* cooling will account for.) Upon the concluding portions of Mr. Mallet's paper, in which

he estimates that the amount of energy afforded by the crushing of the solid crust would be sufficient to account for terrestrial vulcanicity, some strictures were made; but it was held that, if the main proposition had not been proved, these calculations were not of essential importance.

Meteorological Society, May 19.—Dr. R. J. Mann, president, in the chair.—The following papers were read:—On some practical points connected with the construction of lightning conductors, by Dr. R. J. Mann. This paper dealt especially with the material and dimensions of conductors, the nature and influence of points, the essentials of earth contacts, connection with metallic masses forming a part of the construction of buildings, the power of induction in producing return shocks, the dangerous action of metal chimney-pots upon unprotected chimney shafts, and the facility with which houses may be efficiently protected when the defence is made part of the original design of the architect. The conditions which were finally insisted upon as indispensable to efficiency of protection were:—1. Ample dimension and unbroken continuity in the lightning rod. 2. Large and free earth contacts, with frequent examination by galvanometers of the condition of these to prove that they are not in process of impairment through the operation of chemical erosion. 3. The employment of sufficient points above to dominate all parts of the building. 4. The addition of terminal points to the conducting system wherever any part of the structure of the building comes near to the limiting surface of a conical space having the main point of the conductor for its height, and a breadth equal to twice the height of that point from the earth for the diameter of its base. 5. The avoidance of all less elevated conducting divergencies within striking distance of the conductor, and especially such dangerous divergencies of this character as gas-pipes connected with the general mains, and therefore forming good earth contacts.—On certain small oscillations of the barometer, by the Hon. Ralph Abercromby. These small oscillations of the barometer (sometimes called "pumping") have long been associated with gusts of wind, but the precise nature of their action has not been determined. The author gives two examples as typical:—1. Window looking S., wind nearly S., in strong gusts. In this case the first motion of the barometer was always upwards about 0·01 inch, as if the effect of the wind being arrested by the house was to compress the air in the room. 2. A corner house, one window to S., another to W., wind S. in strong gusts. With the W. window open there were violent oscillations, but in this case the first motion was always downwards. On opening the S. window as well, the pumping ceased. The explanation seems to be, that the wind blowing past the W. window drew air out of the room, but when the S. window was opened as much air came in as was drawn out, and the pumping ceased. It is well known to medical men that many acute diseases are aggravated by strong winds; and the author has observed this distress to be associated with the pumping of the barometer. He suggests the following practical methods of palliation:—If windows can be borne open, try by crossing, or otherwise altering the drafts, to diminish the distress. When, as in most cases, windows cannot be open, all doors and windows should be closely shut, as well as the vent of the chimney, if there is no fire; and, if possible, the patient should be moved to a room on the lee side of the house.—Proposed modification of the mechanism at present in use for reading barometers so that the third decimal place may be obtained absolutely, by Mr. R. E. Power.

PARIS

Academy of Sciences, May 10.—M. Frémy in the chair.—The following papers were read:—On the substitution by approximation within determined limits of the relation of variables of a homogeneous function to two variables of another homogeneous function of the same degree, by M. H. Resal.—A letter by M. Faye, on the distribution of temperature on the sun's surface and the recent measurements of M. Langley.—Observations on the Pandaneæ of New Caledonia, by M. A. Brogniart.—On a locomotive on stilts instead of wheels, by M. Tresca.—On a law connected with the work performed by steam-engines, by M. A. Ledieu.—The President then welcomed M. Fleuriais, the chief of the party of observers sent to Pekin to observe the Transit of Venus. M. Fleuriais then read a detailed description of the work done by the expedition and of the journey, which was accompanied by many difficulties.—Observations on the epoch of disappearance of the ancient fauna of Rodrigues Island, by M. Alph. Milne-Edwards.—Memoir on the formulæ of perturbation, by M. E. Mathieu.—On some properties of algebraic curves, by M. Laguerre.—On the toxicological effects of the bark of *Mancône*, by MM. Gallois and Hardy.—On observations made with different Phylloxera, by M. Lichtenstein.—The Minister for Public Instruction transmitted to the Academy a letter, dated Capetown, Feb. 22, 1875, from M. Lanen, and containing interesting data regarding the fauna and the flora of the Kerguelen Islands. These data are due to the observations made by Dr. Kidder, a naturalist who was attached to the Transit of Venus party sent to those islands by the United States.—A note by M. Garnier, on the use of glycerine in the treatment of glycosuria.—On the theory of storms, a reply to M. Faye, by M. Peslin.—On the presence of sulphuric anhydride in the gaseous products of the combustion of iron pyrites; note by M. A. Scheurer Kestner.—On the quaternary lignites of Jarville, near Nancy, by M. P. Fliche.—M. d'Abbadie then spoke on the first results of observations made by M. de Rossi, on the microscopical movements of freely-suspended pendula.—M. Virlet d'Aoust, in relation to the recent catastrophe with the *Zenith* balloon, pointed out the danger in the quick passage through strata of air of variable densities.

May 17.—M. Frémy in the chair.—The following papers were read:—Meridian observations of the minor planets, made at the Observatories of Greenwich and Paris during the first quarter of 1875. The planets observed were the following:—1, 46, 49, 59, 33, 24, 67, 15, 18, 94, 103, 109, 134, 7, 124, 25, 47, 53, 54, 73, 84, and 101. This communication was made by M. Leverrier.—Observations by M. Leymerie, on a note of M. Trutal relating to a Pliocene deposit in the Eastern Pyrenees.—On the swimming-bladder of *Caranx trachurus*, and on the hydrostatic function of that organ, by M. A. Moreau.—On chemical and physiological ferments, by M. A. Müntz.—Experiments and observations relating to glutinous fermentation, by M. A. Baudrimont.—A note by M. de Tastes, on the theory of cyclones.—Anatomical, physiological, and pathological researches on the human ovum in its relation to the diseases of the fœtus, by M. G. J. Martin Saint-Ange.—Observations of the moon and of moon culminating stars, made at Melbourne Observatory, by Mr. Robert Ellery (communicated by M. Leverrier).—On mercury-cataracts, by M. C. Decharme.—A note by M. de Fonvielle, on the precautions to be used when making balloon ascents to a great height.

BOOKS AND PAMPHLETS RECEIVED

FOREIGN.—Zeitschrift für Wissenschaftliche Zoologie: Carl Theodor von Siebold, Albert von Kolliker, und Ernest Ehlers (Leipzig, W. Engelmann).—Jahrbücher für Wissenschaftliche Botanik: Dr. N. Pringsheim (Leipzig, W. Engelmann).—Recherches sur les Phénomènes de la digestion chez les Insectes: Felix Plateau (Bruxelles, F. Hayez).—Le Scoperte del Fusinieri. Influence de la pression de l'air sur la vie de l'homme. 2 vols.: D. Jourdanet (Paris, G. Masson).—Der Venusmond und die Untersuchungen über die früheren Beobachtungen dieses Mondes: Dr. F. Schorr (Braunschweig, Friedrich Vieweg und Sohn).—Etudes Premières et Secondes sur les seiches du lac Léman: F. A. Forel (Lausanne, Rouge et Dubois).—Repertorium für Meteorologie: Dr. H. Wild (Russia).—Annales de l'observatoire Physique Central de Russie: Dr. H. Wild (Russia).—Traversée du Détroit par le Capitaine P. Boyton. (Boulogne-sur-Mer, Charles Aigre).

CONTENTS

THURSDAY, JUNE 3, 1875

THE ARCTIC MANUAL

Manual of the Natural History, Geology, and Physics of Greenland and the Neighbouring Regions. By T. Rupert Jones, F.R.S., and W. G. Adams, M.A., F.R.S. Edited by Prof. T. Rupert Jones, F.R.S., under the direction of the Arctic Committee of the Royal Society. (Published by Authority of the Lords Commissioners of the Admiralty, 1875.)

THE Arctic explorers, to whom we must all give a hearty God-speed now they have started on their journey, besides being supplied with "Instructions" as to the points on which information is most required, and as to the manner in which they may best obtain it, have had compiled for them a most comprehensive "Manual" of what has already been done with regard to the natural history and physics of the northern regions. The time devoted to this work has been short, but the compilers have made the most of it, and their names are guarantees that the information is as complete as possible.

The book consists of a series of reprints of the latest and most trustworthy papers that have been written on the various subjects included. No other form of "Manual" would have been half so useful, even if there had been time to compile it. The limited area within which the exploration is to be conducted has made it possible to include all these in one handy volume. What would not an ordinary naturalist give to have all the previous work that had been done upon the district he was visiting collected together for him, instead of his having to search for it over scattered volumes? and how much more valuable it would be if it were revised up to the latest date by the authors themselves. This is what has been done for the Arctic naturalists, who will be cut off for years from all books but those they take with them, and to whom this work will therefore be of inestimable value. Of course we are not to understand that all that has been written on the natural history and physics of the Arctic regions is here reproduced; that would have been impossible: but in the first part complete catalogues are given, without the descriptions of the genera or species that have been named from Arctic specimens; and the second part, to which less time has been allowed, and which is less complete, contains only the most important portions of the papers or works from which extracts have been made.

It is not the Arctic voyagers, however, who alone will benefit by this Manual. Those who will follow them in thought in their perilous but splendid undertaking will find their interest increased, if this be possible, by the many questions for solution which its perusal will raise in their minds, and they will the more easily compare what was known *before* the expedition with that which we hope will be known after its return.

We proceed to give our readers some idea of the contents of this "Manual." Although the list of papers is no doubt scanty compared with what might be formed of more temperate climes, many no doubt will be astonished that so much has been done in the natural history of these inhospitable regions, far more in proportion than the observations of physical data.

The first part, devoted to Biology and Geology, is divided geographically into three sections; the first, on West Greenland, including Davis' Strait, Baffin's Bay, Smith's Sound, and Kennedy Channel; the second, the Parry Islands and East Arctic America; and the third, East Greenland, Spitzbergen, Franz-Joseph Land, &c. All these between them have 111 illustrative papers, many being double ones. They are arranged in each section zoologically, the first paper being by Dr. Robert Brown, on the Mammals of Greenland, of which there appear to be thirty-one now known, exclusive of introductions by the colonists; all but seven of which inhabit the sea. This paper is followed by two others by the same author, published about the same time (1860), containing his accounts of the species and habits of the Whales, Seals, and Walrus. Many such accounts have been published; they are always read with interest, and we have no doubt much further light will be thrown by the expedition on these animals, some of which are as yet only known by their skulls sent home to museums. There are six species of Greenland Seals, all sufficiently distinct to be placed in different genera, though one is often confounded with another. The chief are the Common Seal (*Callocephalus vitulinus*), the Saddleback, the male and female of which are of different colours, the Grey Seal, and the Bladder-nosed Seal, the latter of which was till lately represented in the Zoological Gardens by a living specimen. There is also the Walrus, large numbers of which used to inhabit British waters during the crag period, but of which only two have as yet been brought alive to England, where they survived but a short time. The Cetacea are more numerous, having sixteen representatives, including the Dolphins and Porpoise. Dr. Brown gives interesting details respecting several of these, of which we need only mention the voracity of the Killer (*Orca gladiator*), out of whose stomach Dr. Eschricht took thirteen porpoises and fourteen seals, the voracious animal having been choked by the skin of a fifteenth. A case is known in which they attacked a white-painted herring-boat in the Western Islands, probably mistaking it for a Beluga or White Whale.

From the Mammals we come to the Birds, the notes on which are contributed in a separate paper by Prof. Alfred Newton, the list being compiled by him from all available sources. The number of true denizens reaches sixty-three, of which, however, only forty-seven occur within the Arctic circle, and not more than thirty-six, if so many, may be expected in Smith's Sound. These are printed in a thicker type to draw attention to them, and short notes are given by which they may be distinguished even by those observers who are not professed naturalists. Prof. Newton is very severe on the former expeditions for "so ingloriously missing their glorious opportunities" in ornithology, "through the absence of special naturalists;" but this will not apply to the present one.

For the catalogues of the Fishes and most of the remaining classes of animals we have to go to Denmark, Drs. Lütken and Mörch, of Copenhagen, being the chief authorities on these branches—and they have both revised their lists to the latest date. The former writer has in preparation an "Ichthyology of Greenland," and the list of fishes here given is only provisional till that is completed. The number reaches seventy-eight, the greater number of course being Teleosteans, and many

inhabitants of great depths, and consequently rare in collections, eighteen only being well represented in those of Britain.

Dr. Mörch's list of the Mollusca, including land, freshwater, and marine forms, reaches a total of 216, which are arranged after his own modification of Latreille's classification. As this is not the classification usually adopted or known in England, it may be well to indicate it. The Mollusca proper are divided into five classes. The first, *Androgyna*, Mörch, includes the five orders: *Geophila*, Fér., or land shells; *Hygrophila*, Fér., or freshwater shells; *Ptenoglossata*, Trochsel; *Gymnobranchia*, Cuv.; and *Pteropoda*, Cuv. The second class, *Dioica*, Latr., is divided into the three orders, *Tænio-*, *Toxo-*, and *Rhachiglossata* of Trochsel, after the characters of their tongues. The third class, *Exocephala*, Latr., is divided in the same way, into *Rhipido-* and *Heteroglossata*; while the remaining two classes, *Cephalopoda* and *Acephala*, are undivided, although there are enumerated species of the different orders as usually distinguished in the latter class. The *Brachiopoda* figure for four species in addition to the above, under the title of *Brachionopoda*. The *Tunicata* number thirteen species, and require revision, while the *Polyzoa* mount to sixty-three. Of the Insects nothing is recorded since Schiödte's list in 1857 of 114 species; of Arachnida there are almost none but a few Acari. The list of Crustacea is a large one, and has been revised by Dr. Lütken for this Manual. The whole number is 184, of which no less than seventy are *Amphipoda*. Yet this list is plainly incomplete, the *Ostracoda* being represented by one species only, while in the next paper Dr. Brady enumerates twenty-four from their shells. The other classes of animals have similar lists. In the Annelids most families are represented by a few species; the various Entozoa are tabulated. The Echinoderms are thirty-four, containing only one Echinid: the remaining lists are short ones, except that of the fixed Hydrozoa, and the Sponges, which are pretty numerous. It is useless, of course, to catalogue "species" of Foraminifera, and only a few notes are accordingly given of the various generic forms which have been met with at various depths, with a description of the nature of the materials in which they occur.

From animals we pass to plants. The first paper is the well-known one by Dr. Hooker, "Outlines of the Distribution of Arctic Plants," from the Linnean Society's Transactions for 1861, which has been reprinted with little alteration, chiefly from want of time, the more recent discoveries being given in foot-notes. The list of flowering plants contains those from the districts of Arctic East America and Greenland only, which number 552, of which about two-fifths are Monocotyledons, and the remainder Dicotyledons. Mr. Taylor's paper, on the Plants of Davis' Strait, though without the generalisations of the former, gives more details on the habitats and localities of the specimens; but this paper also is one of old date (1862). The Cryptogams are enumerated in various papers on the several sections to which separate students usually devote themselves; the most important being Dr. Lindsay's, on the Lichen Flora of Greenland and other Arctic Regions, from the Transactions of the Botanical Society of Edinburgh for 1869. As lichens will grow where nothing else will, their various species may naturally be expected to make a large figure in an Arctic flora; and so they actually do, as they number by themselves half as many as all the flowering plants together. The Diatoms, which in their vast numbers cause the discoloration of some portions of the Arctic seas, form the subject of another interesting paper by Dr. Brown.

When we reach the portion of the Manual relating to Geology, we find some part of the information to be of very ancient date, belonging to the days of Flætz-Trap-Formation and other exploded terms, which now convey no information whatever. The interest of these papers, written by Sir Charles Giesecke in the beginning of this century, is mineralogical. He was a careful collector and diligent observer, and his records are still valuable. One of his chief discoveries was an easily fused mineral he named cryolite, which is now an abundant source of aluminium. To this two papers are devoted. Shortly following these we have Dr. Sutherland's paper, no less valuable because some twenty years old, on the Geological and Glacial Phenomena of the Coasts of Davis' Straits and Baffin's Bay, which contains many observations on the ice-phenomena both of small and large masses. The Miocene Flora of Greenland, so admirably described by Prof. Oswald Heer in his "Flora Fossilis Arctica," and catalogued in other works, cannot of course in a small Manual like the present receive more than a comparatively brief notice, nor can it be needed, as it is an essentially standard work. There is also a Cretaceous Flora catalogued from the "Kome Formation" of the north coast of Noursoak Peninsula. Undoubtedly the most interesting paper in this section is that of Prof. Nordenskjöld, extracted from the *Geological Magazine*, in which he gave an account of his fruitful expedition to Greenland in the year 1870. The united papers that detail his experiences are together of considerable length. He made one of the very few attempts that have yet been made to enter the great continental icefield, and succeeded in passing over thirty miles, the interesting details of the journey being here recorded; and much valuable information was thus obtained. The new expedition will have great opportunities of such explorations, which is a reason for regretting the absence from it of any professed geologist. Prof. Nordenskjöld gives an account also of the various strata of the coast, which exhibit beds of Cretaceous and Miocene age, with some basalts which are associated with them. One of the most interesting discoveries made by him was that of three large masses of meteoric iron at Ovifak, of which a woodcut and analyses are here given, with full accounts of its various points of interest. This latter recital is very naturally followed by that portion of Dr. Flight's recent contributions to the *Geological Magazine* on Meteorites, which relates to those found in Greenland. This contains the results of the newer Swedish Expedition of 1871, together with further details about the stones themselves, as compared with other meteorites. The two chief remaining papers in this division are, first, a valuable abstract of geological notes on Noursoak Peninsula and Disco Island, by Dr. Robert Brown, which is only just published in the Transactions of the Glasgow Geological Society, and contains a succinct account of the geology of that part of Greenland as made out by various explorers; and secondly, a

collection of notes by Henry H. Howorth of the several observations that have established the fact of the rising of the circumpolar land.

We have now passed in review the chief portion of this Manual, which occupies 500 out of its 750 pages, and relates to that portion of the Arctic regions whither the explorers are in the first instance bound. The remaining portion of the Natural History division—occupied with Parry Island and East Greenland—consists of shorter papers and far barer catalogues. These perhaps require no observations beyond noticing the fact—recently pointed out also by Mr. De Rance in our columns—that the various geological periods are much better represented in these latter districts, there being Silurian, Carboniferous, Triassic, and Jurassic, as well as Cretaceous and Tertiary rocks; and consequently we have lists of fossils supplied with which any that may be discovered may be compared. The last of the Natural History series is an extract from Mr. Woodward's paper on Glaciation, the object of the insertion of which, as it is entirely theoretical, it is difficult to understand, unless it be to give the explorers some idea of the kind of questions on which some of their geological and glacial observations may be expected to throw light.

There are two things that strike one in reading these long catalogues—(1), that he must be a well-informed naturalist to whom many of the names which belong to all classes and kingdoms of life are anything more than names; and (2), arising from this, what an advantage there is in having specific names at least as far as possible descriptive.

The second part of the Manual, relating to Physics, requires of course less detail, and is included in a far smaller number of pages. It is not constructed on exactly the same plan as the first part, but consists in a great degree in descriptions of the observations and results, instead of reprints of the original papers; nor is it so exhaustive. It is divided into eight portions, relating respectively to Meteorology, Temperature of the Sea, Formation and Composition of Sea-water Ice, Tides and Currents, Geodesy and Pendulum Experiments, Observations on Refraction and on Air, Terrestrial Magnetism, and the Aurora Borealis. Under the head of Meteorology we have a few scattered notes on the results of the numerous previous expeditions with the thermometer, barometer, &c., and a valuable table on the mean temperatures of various stations for the several months of the year. The information as to the temperature of the sea is still more meagre, and it seems to us that more might have been included with advantage. The papers selected on the Physical Properties of Ice are extremely suggestive and valuable, consisting partly of observations in Arctic regions as to the freezing-points of sea-water, and the compositions of the resulting ice and the remaining liquid, and partly of similar experiments in the laboratory.

The information also on the tides and currents is pretty full, showing what methods have been adopted in various expeditions for determining the former accurately and with what results. There are also papers of suggestions as to the probable directions and amounts of both, and the best places for observation, and on the Meteorology and Hydrography of the Austro-Hungarian North Polar Expedition. The part on Magnetism is on the same model as the last mentioned, and is equally, if not more valuable. The last chapter, on the Aurora Borealis, is the best of all. Besides the ordinarily phenomenal observations already made, great attention is naturally paid to the spectrum of the Aurora, its connection with electrical discharges, together with Angström's views of its origin as explained in NATURE (vol. x. p. 246), and the opinions of Prof. Herschel and Mr. Capron, as well as those of MM. Lemström and Wijkander, deduced from observations made by them in the different Swedish expeditions, all of which are here given as fully as possible.

Such is the book with which, in addition to all others, the Arctic explorers are supplied. It is a library in one volume such as one does not often see. The mass of material it contains is something marvellous, and all is condensed as much as is advisable. The compilers must have had hard work, but they may congratulate themselves on the result. They have practically said to the Arctic voyagers—"This is what we have; go and obtain more for us." May they be successful, and return with a full cargo of information, which, if it were packed as tight as in this Manual, would not take up much room in comparison with its high value.

LAWSON'S "NEW GUINEA"

Wanderings in the Interior of New Guinea. By Capt. J. A. Lawson. With Frontispiece and Map. (Chapman and Hall, 1875.)

It is not often that a work of fiction calls for notice in the pages of NATURE; but we have here an exceptional case. This book has been favourably noticed in some of the daily and weekly papers as a genuine narrative of travel and an addition to our knowledge of an almost unknown region, and it therefore becomes a duty to inform our readers that it is wholly fictitious. It is not even a clever fiction; for although the author has some literary skill and some notion of the character of savages, he is so totally ignorant of the geography and the natural history of the country he pretends to have explored, and so completely unacquainted with the exigencies of travel and exploration in trackless equatorial forests, as to crowd his pages with incidents totally unlike any that occur to the actual explorer, and with facts altogether opposed to some of the best established conclusions of physical geography. We proceed to give proofs of the accuracy of these statements. First, as to his geography. He starts from a point a little to the east of Torres Straits, of which he is so injudicious as to give the latitude and longitude (both to seconds) from his own observations. He also gives a map of his route, but without scale or meridian line. He describes himself, however, as travelling generally northwards with only such divergences as the country necessitated, and we may therefore take it that his route was nearly north, as it should have been to cross the island. But although he gives no scale to his map, he (again injudiciously) gives the dimensions of a large lake, along one side of which he travelled, as "between 60 and 70 miles long, 15 to 30 broad," which being laid down on his map furnishes an excellent scale, and shows that the total distance from his starting point in a straight line to the place he professes to have reached must have been somewhere between 560 and 620 miles.

Now, the total width of New Guinea is here 380 miles only, and the longest distance possible to go without reaching the sea is just about 620 miles, which takes you to the shores of Geelvinck Bay.

The centre of New Guinea is about 6° S. of the equator, and is almost certainly a forest region throughout and abundantly watered. In this equatorial belt all round the globe the temperature is not excessive, 96° or 98° being the extreme daily limit, while the nights are almost invariably cool (70° to 76°). The greater part of the country here described is, however, said to be open plains with only occasional forest tracts; water was not found for a whole day's journey, even at the foot of a mountain range 10,000 feet high, and the ordinary daily temperature is said to have reached 106° to 109° and 115° in the shade. He describes a terrific storm of hailstones as large as hens' eggs, not on the mountains, but in the low country about 7° S. latitude.

His mode of travelling is as extraordinary as his geography. After the statement that in the tropics "early morning and evening are the only times when it is possible to travel," he assures us that he started at 3 A.M., and in the evening continued his journey till 9 P.M. This gives two-and-a-half hours in the morning and the same at night of total darkness, in an unknown, pathless, tropical country, and he even ascends part of a dangerous mountain full of fissures and huge rocks, till nine o'clock at night! The country, too, was full of venomous snakes; and huge scorpions a foot long, whose sting was certain death, were very abundant; and as these last are nocturnal animals, travelling in darkness among fissured rocks and dense vegetation must have been exciting. But then we are told that he carried a lanthorn, and by means of this artificial illumination it is to be supposed the whole party made good progress and baffled the scorpions.

More marvellous still is the ascent of Mount Hercules, 32,783 feet high. He starts with one native from the foot of the mountain at 4 A.M., carrying "food, water, arms, and blankets," and ascends 14,000 feet by nine o'clock! At 15,000 feet they came to snow, but continued on for many thousand feet more, and by 1 P.M. had reached a height of 25,314 feet, the temperature being 22° below freezing. This is certainly good climbing, as it is just 4,000 feet higher than Chimborazo from the sea-level, and more than twice as high as Mont Blanc is above Chamouni. The Alpine Club must hide their diminished heads after this. Of course, having turned back at one o'clock, our travellers arrived safely at their camp at 7.30 P.M. A tinted view of this wonderful mountain forms the frontispiece to the book.

Having digested this Alpine feat as best we may, let us turn to Capt. Lawson's account of the natural history of the island. It may be premised, for the benefit of non-zoological readers, that New Guinea belongs to the Australian region, and that with the exception of bats and a wild pig, all the known mammalia are marsupials, four species of kangaroos, several species of *Cuscus* (an animal somewhat like an opossum), and some smaller marsupial forms being known. The coasts have been visited for centuries, and considerable excursions have been made in the interior of the northern part of the island, while the southern portions have also been several times visited by our various surveying parties. The islands all round it agree in this exclusion of all mammalia but marsupials. But Capt. Lawson tells us quite a different tale. He met with no solitary kangaroo or Cuscus all through New Guinea, but he everywhere encountered deer of several species, wild buffaloes, wild goats, wild cattle of a new species, hares, foxes, a wonderful new tiger, long-tailed monkeys, and huge man-like apes! Of birds we have, quite correctly, Cockatoos and Birds of Paradise, but along with these, pheasants, woodpeckers, and vultures, the two former not known within a thousand, the latter within two thousand miles of New Guinea. The natives, too, have great herds of hump-backed cattle, and far in the interior many of them speak Dutch!

Hardly less absurd are Capt. Lawson's wonderful hunting feats and hairbreadth escapes. The monkeys of New Guinea seem remarkable for waiting to be shot at, although, as the natives have guns and shoot them for food, they would in other countries have become wary. Yet our author goes out with a native chief to shoot monkeys, and in a couple of hours they bag a score and wound several others. Again, in an hour's shooting he kills "thirty-nine ducks, five ibises, two storks, seven kingfishers, and three new birds." The deer are seen in "herds of two or three hundred," the wild goats generally go in "flocks of seventy or eighty!" A herd of at least ten thousand buffaloes was seen, and in a single tree more than a thousand hanging nests of one species of bird were counted, each nest, too, containing several distinct families. Capt. Lawson is tossed and then trampled on by a wild buffalo, and when recovered so that he could "walk a few paces, leaning on the arm of one of his attendants," he goes fishing, and in two hours "pulled out over a hundred fish, the largest a yard long," not to mention many large fish which broke away from the hook. A huge New Guinea tiger gets him in its clutches, but though the animal was larger than a Bengal tiger, he of course escapes, though "drenched with the Moolah's blood." He preserves the skin, which is "marked with black and chestnut stripes on a white ground," and this skin is "one of the few specimens he has succeeded in bringing to Europe." Wonderful birds, snakes, and insects are also described, sometimes very minutely, but not one of them at all resembles any of the known denizens of New Guinea. Here is a butterfly for example: "The largest specimen I obtained, whose wings measured exactly twelve inches across, was black, with a red border to the wings and red bands round the body. In the centre of each wing were three light blue spots arranged in a triangle. The body of this fly was as thick as my thumb, and six inches in length. The feelers were twelve inches in length, *and curled into three coils.*"

As if to complete his own refutation, our author states that he returned to the coast with a party of natives who were conveying, among other merchandise, skins of "birds, monkeys, &c.," and that two or three Dutch traders, as well as many Malays and Chinese, come there every year. This part of New Guinea is therefore in constant communication with the rest of the world, yet the existence in the island of monkeys, apes, deer, buffaloes, goats, and tigers, has remained totally unknown till the secret was revealed to us by this enterprising and veracious traveller.

ALFRED R. WALLACE

OUR BOOK SHELF

Vestiges of the Molten Globe. By W. L. Green, Minister of Foreign Affairs to the King of the Sandwich Islands. (Stanford and Co., 1875.)

It is a pity that books of this sort are published, as they can do no good. It is one of that class which attempts to account for the general features of the earth by some extravagant hypothesis, for the proof of which some superficial observations of well-known facts and some show of quotations from well-known writers are all that is offered. Who besides the author can believe that the shape of the earth, deprived of its oceans, would be a tetrahedron, the four angles representing the four continents? Yet the author announces himself as following in the footsteps of Elie de Beaumont in his theory of the *réseau pentagonal*, as the following lucid sentence on page 2 shows:—"The form (of the earth) is included in his *réseau triangulaire*, and is, as I propose to show, the six-faced tetrahedron; the easterly sag or twist of the southern hemisphere on a twin plane, the apparently macled form of the crystal, having caused the lines of relief and depression of the earth's surface to elude solution whilst the *réseau* of that crystal in its simple form alone was applied to them." We quite agree with the author that "only the imperfection of the ideas or of the language in which they are conveyed can prevent the following pages being intelligible to every reader." However untenable De Beaumont's theory was, it was conscientiously and laboriously worked out, and the conclusions were commensurate with the offered proof, even if they were erroneous; but Mr. Green, who would be his follower and improver, jumps to conclusions far wider on the basis of supposition only. The present short volume is only the first part of three that are promised on the figure of the earth, volcanic action, and physiography; and we must hope that the second part, at least, which is to contain "observations of the great active volcanoes and the great extinct volcanic range of the Hawaiian group," which the author must have had good opportunities of making, will be somewhat more solid than this first. Mr. Green is plainly capable of better things than wild speculation, which anyone can make and no one can prove. There are no doubt many remarkable features in the distribution and shape of land and the direction of its coast lines, some of which are here pointed out; but the meaning of these things will only be arrived at by a wider knowledge of facts and sober induction from them. The large map that accompanies the volume shows some of these features well, and is beautifully executed.

Stanford's Elementary Atlases. I. Physical Atlas (sixth edition); II. Outline Atlas; III. Projection Atlas; IV. Blank Sheets for Maps. By the Rev. J. P. Faunthorpe, M.A., F.R.G.S. (London: Edward Stanford, 1875.)

This is really an admirable apparatus, not merely for the purpose of teaching the construction of maps, but for the giving of a real knowledge of what Physical Geography means, and for the conveyance of an impressive idea of the prominent physical features of the particular countries embraced in the set of maps. There are sixteen maps altogether, and in the Physical Atlas the chief physical features of the various countries are clearly brought out—mountain ranges, table-lands, and river-courses. The mountain ranges are simply but sufficiently indicated by thick lines, the principal summits being shown by small circles; the table-lands are shown by simple shading. Besides these features, each map contains one or more of the principal cross-sections of the country, which convey a vivid idea of its conformation. Prefixed to the Physical Atlas are a few useful hints on Map-drawing, on Mercator's Projection, on the Shape and Position of the Land Masses, and a few notes illustrating each map. Atlases II., III., and IV. are intended to lead the student gradually to skill in map-drawing, and are well calculated to serve the purpose. Anyone who goes faithfully through the course indicated by this excellent set of books will have a more real knowledge of the main features of the land-masses of the globe than any amount of mere reading can give. The fact that the Physical Atlas has reached a sixth edition, which contains several new maps and additional letterpress, proves that Mr. Faunthorpe's design has been appreciated.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

The Meteors of November 14

The writer some time since called attention to the fact that the dates of certain meteoric showers, given by Humboldt and Quetelet as belonging to the November stream, indicated the existence of two distinct and widely separated clusters moving in orbits very nearly identical. The years thus designated were 1787, 1818, 1820, 1822, 1823, 1841, and 1846. As the last two were subsequent to the great display of 1833, the meteors seen were noticed only in consequence of their being specially looked for; and as the number conformable to the radiant of the Leonids is not given, there may be some doubt whether those observed really belonged to the November stream. The former displays occurred before the periodicity of such phenomena had been suspected, and the number of meteors would seem to have been considerable. As the shower of 1787 preceded by twelve years the great meteoric fall witnessed in South America by Humboldt, the group from which it was derived had passed beyond the orbit of Saturn at the time of the latter display. The phenomena of 1818, 1820, 1822, and 1823 indicate that, as in the case of the major group, which passed its descending node between 1865 and 1870, the meteoroids are extended over a considerable arc of their orbit. From November 1787 to the middle of the nodal passage of 1818–1823, is about $33\frac{1}{3}$ years—a period nearly the same as that of the principal cluster. These facts alone were regarded by the present writer as giving reasonable probability to the hypothesis of an approximate identity of orbits. In Nature, vol. xi. p. 407, it was shown that the meteor-showers of October 855 and 856 were probably derived from the stream of Leonids, and it is certainly remarkable that the interval from 855 to 1787 is equal to twenty-eight periods of 33·293 years. Again, the shower observed in China, Sept. 28, A.D. 288, making proper allowance for the nodal motion, corresponds to the same epoch; the interval between 288 and 855 containing seventeen periods of 33·35 years. In view of the fact that the shower from this cluster was due between 1851 and 1855, the following extract from the writer's note-book is not without interest:—

"Newark, Delaware, Nov. 13, 1852. . . . On the evening of the 11th, from 7 to 10 o'clock, an aurora borealis of ordinary brilliancy was constantly observed. About midnight the sky became overcast with clouds, thus preventing our watch for meteors which we were about to commence. On the 12th, from about 3 to 9 o'clock A.M., rain fell almost incessantly. About noon the clouds broke away, and the night between the 12th and 13th was quite clear. During six hours—from 10 P.M. to 4 A.M.—constant watch was maintained at four windows, facing north, south, east, and west. From 10 to 1 o'clock the observations were conducted by Prof. Ferris and myself with assistants. At 1 the place of Prof. Ferris was taken by Prof. Porter, who remained, with myself and assistants, till 4. We observed—

From 10h. to 11h.	...	...	20 meteors.
,, 11 ,, 12	...	...	35 ,,
,, 12 ,, 1	...	...	40 ,,
,, 1 ,, 2	...	...	52 ,,
,, 2 ,, 3	...	...	75 ,,
,, 3 ,, 4	...	...	59 ,,
Total	...	...	281

When the meteors were most numerous, near 3 o'clock, the common point of divergence in Leo was distinctly observed."

I may here add, although the fact is not stated in my memoranda, that the conformable meteors, or a majority of them,

were seen near the radiant, and that they were generally smaller and had shorter tracks than the November meteors observed between 1865 and 1870. The number seen was too small to be called a shower; at the maximum, however, the fall per hour was nearly double that of ordinary nights. In short, I have no doubt that they were Leonids, and think it highly probable that they were derived from a distinct cluster which passed its perihelion in 1787 and 1820. We have therefore nine recorded meteor-falls which indicate the existence of a second cluster of Leonids, viz., those of A.D. 288, 855, 856, 1787, 1818, 1820, 1822, 1823, and 1852. The showers of 855 and 856 may be somewhat doubtful. If derived from the same meteor-cloud as the others, the dates would indicate considerable perturbations either by Uranus or the earth. The displays have been much less conspicuous than those of the major group, and hence the phenomena have been less frequently observed. The period is about 33·33 years, while that of the other swarm, according to Newton, is 33·25 years. Since their separation, therefore, the latter has gained nearly two-thirds of a revolution in their relative motion. The estimates which have been made in regard to the recent entrance of the cluster into the planetary system must consequently be rejected. DANIEL KIRKWOOD

Bloomington, Indiana, U.S.A., April 20

Systems of Consanguinity

IN NATURE, vol. xi. p. 401, I find a notice of the third edition of Sir John Lubbock's valuable work on the "Origin of Civilisation," in which the following paragraph occurs:—"The facts with which he deals in this chapter [a new one in that volume] have been taken from the voluminous work of the American author, Mr. Morgan; but Sir John Lubbock, putting aside Mr. Morgan's theorising, has submitted a view of them of his own. This, in the main, and as far as it goes, we think, he has made out."

In the same article the following paragraph also occurs:—"One of Mr. Morgan's theories (for he has, or seems to have, two which it is no business of ours to reconcile with each other) is, that these systems are, to use the words of Sir John Lubbock, 'arbitrary, artificial, and intentional.'"

These statements, to the last of which with your permission I desire to reply, present the "American author" both harshly and unfairly to the British public. The interpretation of these systems of consanguinity, thus ascribed to me, is not mine; neither is the interpretation given in my work on "Systems of Consanguinity."

There are three or four places, and perhaps more, in that volume in which I speak of the system of a particular people as "artificial and complicated," and as "arbitrary and artificial," without the qualification in each case which should, perhaps, have been inserted. Thus, commenting on the same system (Con. p. 392), I remark that "the chain of consanguinity has been followed with great particularity, that the artificial and complicated character of the system might be exhibited, as well as the rigorous precision with which its minute details are adjusted." One who had read my work through could not have been misled by this statement, which was intended to characterise this system as it appeared on its face, and apart from all considerations respecting its origin. On the next page but one (p. 394) the same statement is repeated and qualified as follows: "As a plan of consanguinity it [the same system] is stupendous in form and complicated in its details; and seemingly arbitrary and artificial in its character when judged by ordinary standards."

In a single and final chapter of that work (pp. 467-510), entitled "General Results," I discussed the three great systems of consanguinity found in the principal families of mankind, and indicated some of the general conditions they seemed to warrant. My interpretation of these systems will there be found. To this chapter a person would naturally turn if he wished to know the views of the author on the precise question whether the systems were to be regarded as artificial or natural. Among other things, it contains what is prudently called a "conjectural solution" of the origin of the Malayan system of consanguinity, and also a similar solution of the origin of the Turanian system. These solutions are presented and discussed in connection with a series of fifteen prominent institutions and customs of mankind, articulated in a sequence in the order of their probable origination. It commences with "I. Promiscuous Intercourse"; "II. Intermarriage, or Cohabitation of Brothers and Sisters;" and ends with "XV. The Overthrow of the Classificatory System of Relationship, and the Substitution of the Descriptive." In it are enumerated several successive forms of marriage, several successive forms of the family, and the three systems of consanguinity in their order of relation. It was designed to illustrate the course of human progress from savagery to civilisation; one form of marriage being followed by another, one form of the family by another, and one system of consanguinity by another. It is a sequence of human progress through the slow accumulations of experimental knowledge.

At the end of the solution of the origin of the Malayan system, which is founded upon the assumed intermarriage of brothers and sisters in a group (the second member of the sequence), occurs the following statement (p. 482):—"Every blood relationship under the Malayan system is thus explained from the nature of descents, and is seen to be the one actually existing, as near as the parentage of individuals could be known. The system, therefore, follows the flow of the blood, instead of thwarting or diverting its currents. It is a natural rather than an arbitrary and artificial system." The reader will notice that it was this form of marriage which created the Malayan system.

Again, at the end of the solution of the origin of the Turanian system, and after showing that the latter was derived from the Malayan, occurs the following statement (p. 486): "If the progressive conditions of society during the ages of barbarism, from which this solution is drawn, are partly hypothetical, the system itself, as thus explained, is found to be simple and natural instead of an arbitrary and artificial creation of human intelligence."

In prosecuting this investigation one of the questions to be determined was whether these systems were artificial or natural. If the former, they are without ethnological value; but if natural systems, showing the relationships which actually existed when they were respectively formed, then they would possess immense value, because they concerned and demonstrated a condition of ancient society of which previously we had no definite conception. From each system, in such a case, can be deduced, with almost unerring certainty, the form of marriage and of the family in which it originated. It was by this course of reasoning that I discovered the necessary antecedent existence of the intermarriage of brothers and sisters in a group to account for the existence of the Malayan system of consanguinity. This fact gives us the starting-point in which ancient society commences, with the proof that it did so commence. Hence the second member of the sequence above-named. This sequence on its face, and these solutions in express terms, treat these systems as natural in every respect.

In an address before the London Anthropological Institute in 1871 upon the contents of the same volume on Consanguinity, Sir John Lubbock places me in the same position, and leaves me there. He remarks in that address (Journal of A. I., 1871, p. 6), which I presume forms the basis of "the new chapter," that "Mr. Morgan, from several passages, appears to regard the system as arbitrary, artificial, and intentional;" from which he takes occasion to dissent. I find in that somewhat elaborate address no reference whatever to the solutions named, and none whatever to the sequence. I am persuaded they must have escaped his notice. LEWIS H. MORGAN

Rochester, New York, April 19

The Migration of Species

IT has probably been the experience of most who have undertaken a voyage to sea, to have observed land-birds and insects far from the nearest coast, either in course of transit or resting on the vessel. Many travellers have observed these visitants, and their records have proved valuable biological facts bearing on the occasional migrations of species and their consequences as has been pointed out by Mr. Darwin. But it is more than probable that this dispersal of land species over extremely wide areas of sea is far more constant and less occasional than we are at present justified in affirming from the facts as yet collected. Unfortunately, however, we glean very little biological information from the great mercantile marine service of this country, an assemblage of which we are so justly proud, and it is only by costly Government expeditions that we become acquainted with facts that remained and would have remained unnoticed by the immense number of sailors who leave our shores. Nor can we feel surprised at the result when we recollect that biology is scarcely a subject thought necessary to form part of a mariner's education. A good instance is afforded by the results of the voyage of the *Beagle*. An impalpable powder fell upon the ship off the Cape de Verd Islands. This powder must have fallen upon many ships before; but Mr. Darwin being on board the

Beagle, it was collected and sent for inspection to Ehrenberg, and results of great scientific value accrued. Had our great philosophic naturalist not been there, this dust might still have fallen on ships to the present day, been swept away as a nuisance, and unrecognised as of any possible interest. That errant species must frequently visit vessels was shown me on a voyage to the East a few years ago. Thus, in the early part of September, in about lat. 12° N. and long. 26° W., a dove flew on board, which, after resting for a short time, again pursued its journey. In about lat. 9° N. and long. 25° W. a moth, apparently *S. convolvuli*, reached the vessel just before the arrival of a squall. In reply to my inquiries, both the officers and crew stated that these were simply very common occurrences.

I think we may feel confident that most vessels sailing this course meet frequently with like objects, and the interest would be increased by finding whether the same were observed by vessels still further from the nearest land. Could some means be devised for obtaining records of these migratory species, or could some large shipowner be induced to have the same carefully recorded in the log-books kept on board his vessels, I feel little doubt that we should be astonished by the number and constancy of these wanderers from other lands. The entry in the log-book would ensure the date and approximate latitude and longitude which would be necessary factors in dealing with this biological question, and would doubtless bear further proof to Mr. Darwin's view of colonisation by chance or occasional visitants.

So much might be done by some of our present means of unendowed research that it seems weary waiting for the day when a broader education will tend to induce our sailors to reap that abundant harvest of scientific information which they so constantly have the means of acquiring. There is surely some branch of science which might be indebted to every vessel that sails from this country on a foreign voyage, could the preliminary information and impetus for inquiry be given to the officers or crew. I believe the "Religious Tract," or some kindred society, provides many of our vessels with devotional literature; could not our learned societies also compile and provide some scientific works and questions for solution which might be placed in the hands of our sailors, thus affording a pleasure for a long voyage, and producing effects to be appreciated by science at home?

We should not expect the results of a "*Challenger* Expedition," but then Government outlays for that purpose are sometimes few and far between. W. L. DISTANT

Streatham Cottage, Buccleuch Road, West Dulwich

Murænopsis tridactyla

WITH reference to Mr. Kent's letter in your last number (p. 69), I beg leave to point out to you that it is very doubtful, according to the best authorities, whether the so-called *Murænopsis tridactyla* is even *specifically* different from *Amphiuma means* (*i.e.* the two-toed form of the same animal). Of the latter this Society have had several living specimens in their collection. One of them (purchased December 6, 1870) is still living in the Society's Gardens. P. L. SCLATER

Zoological Society of London

Hardened Glass

THE account of hardened and malleable glass given in NATURE, vol. xi. p. 474, interested me greatly.

It seems hardly possible that a change in the molecular constitution of glass can take place without affecting its optical properties. May not this glass, therefore, possess refractive and dispersive powers unlike those of the kind usually employed in lenses? If it can be made of sufficient purity and is found to have a higher refractive power, it will enable us to make thinner lenses with smaller curves, thus contributing to the further improvement of optical instruments. Yorkshire Exhibition "Guide"

WILL you kindly allow me, as a member of the Science Committee of the Yorkshire Exhibition of Arts and Manufactures, held at Leeds, to point out that the Yorkshire "Guide" referred in NATURE, vol. xii. p. 76, is entirely an unofficial publication. No competent member of the Committee was applied to for information respecting palladium or any other exhibit. The first intimation the Committee had of the wild statements contained in the "Guide" was received from a member who purchased a copy in the usual way, and immediate steps were taken to secure that more trustworthy information should be contained in future editions of the "Guide," unofficial though it be. You will, I think, see that it is rather hard that the Committee should, as by inference they may be, be made responsible for the statements you indicate, and will, I hope, give me space for this repudiation of them.

H. POCKLINGTON

Primroses and Cowslips

IN answer to Mr. J. J. Murphy's inquiry in NATURE of May 13 (vol. xii. p. 34) I beg to state that the locality in which, as far as I am aware, no primroses are found, is formed by the outcrop of the chalk in the south of Cambridgeshire and north of Hertfordshire, and is bounded on the north and south by the outcrop of the chalk marl and the edge of the London Basin, and east and west by the Great Eastern and Great Northern main lines; it is, from the nature of the underlying beds, very dry. I have always thought, but perhaps without foundation, that primroses are not generally found in the districts in which cowslips are common, and *vice versâ*, and Mr. Murphy's remark seems to bear out this.

I have not noticed any instance of the removal of the ovules of cowslips by birds; and even primroses, in other parts of the garden than those first attacked, have been left untouched.

Odsey, near Royston, Herts H. GEORGE FORDHAM

OUR ASTRONOMICAL COLUMN

THE MELBOURNE CATALOGUE.—We have received the "First Melbourne General Catalogue" of stars, which is founded upon the observations taken with the Transit Circle under the direction of Mr. Ellery, the Government Astronomer, at the New Observatory of Melbourne, between the middle of the year 1863 and the end of 1870. It has been reduced and prepared for publication by Mr. E. J. White, the first assistant, from the materials printed in vols. ii. iii. and iv. of the Melbourne Observations. Vol. i. contained a catalogue of 546 stars resulting from the meridian observations taken previous to the removal of the Observatory to its present site, and called the "Williamstown Catalogue:" in the new publication we have the positions for the beginning of 1870, of 1227 stars, with few exceptions observed at least three times, and accompanied by the terms of precession to the third order, proper motions, and Bessel's reduction-constants (as in the British Association Catalogue), with the synonyms in Lacaille, Piazzi, Brisbane, and Johnson. Great care appears to have been taken in calculating the precessions from the mean year of observation to the epoch of the catalogue, and a detailed account of the process employed is given in the introduction. The proper motions of the stars have also been discussed where the means were available, the more uncertain results being distinguished from those possessing greater claim to acceptance by enclosure in parentheses.

Many of the most interesting stars of the southern heavens are included in this Catalogue, and we note that the remarkable one ϵ Indi has not been overlooked. In this case the recent Melbourne observations, as compared with Jacobs' at Madras in 1852, assign an annual proper motion of 4″·58 in arc of great circle, thus quite confirming values previously obtained from less reliable data. We hope that at no distant period an attempt will be made to determine the parallax of this star. Large proper motion is indicated for the stars B. A. C. 5719, Aræ, and 7816, Indi; but on comparing the Melbourne positions with those in Gilliss's Santiago Catalogue, in the Washington volume of observations for 1868, not mentioned by Mr. White amongst the authorities he had consulted, it is not confirmed in either case.

The "First Melbourne Catalogue" is a handsome specimen of typography from the Government Printing Office. It must form an essential work of reference for every southern astronomer, who has now, with the "Cape

General Catalogue," two authorities supplying him with excellent positions of a large number of stars.

THE COMET OF 1533.—In the catalogues of the orbits of comets we find two sets of elements for this comet, both deduced from the observations of Apian between July 18 and 25, which are contained in his rare work, *Astronomicum Cæsareum*. The first orbit is by Douwes, who assigned *retrograde* motion, but in the *Berliner Jahrbuch* for 1800, Olbers gives another orbit, equally satisfactory as regards representing Apian's observations, in which the heliocentric motion is *direct*, and he appeared to think it was not possible to decide which of the two is to be preferred. In addition to Apian's account of this comet we have a brief one by Gemma Frisius, who states that after having been seen about the beginning of July in 5° (or rather, as Pingré corrects him, in 15°) of the sign Gemini, near the star Capella, with 24° of latitude and 48° north declination, it passed by a westerly motion, or contrary to the order of the signs, to the constellation Cassiopea, which it traversed, finally disappearing in Cygnus. Fracastor has also left us an account of the comet's track, though there is some ambiguity about it. Since Olbers calculated the orbit the Chinese observations have been published, in the first instance by M. Edouard Biot, in the additions to the *Connaissance des Temps* for 1846, and more recently in Mr. Williams' work upon Cometary Observations in China, and it would appear that the comet moved to the vicinity of π Cygni, and was last seen on Sept. 16. If we compare the elements of Douwes and Olbers with the track thus roughly defined, we see that the retrograde orbit of Douwes is hardly probable, and that possibly a modification of the direct orbit of Olbers would be found to sufficiently represent the path of the comet, according to Apian, Gemma, and the Chinese Annals.

OCCULTATION OF VENUS.—Mr. R. Meldola, of the Royal Society Eclipse Expedition, writes that the occultation of May 2 was partially observed by Prof. Tacchini and himself from the P. and O. steamer *Peshawur* in the Arabian Sea. The moon was obscured by clouds at the time of immersion; the last contact took place at 16h. 15m. 6s. local mean time. Ship's position furnished by Capt. White—long. 77° 3′ E., lat. 6° 48′ 18″ N.

OUR BOTANICAL COLUMN

PHENOMENA OF PLANT-LIFE.—The expansive power of growing vegetable tissue is something marvellous, if the experiments undertaken by Mr. Clark, president of the State Agricultural College of Massachusetts, are perfectly trustworthy. If his appliance for measuring the force exerted by a growing pumpkin was not at fault, the greatest weight lifted by the pumpkin in the course of its development was nearly two-and-a-half tons. Apparently the greatest care was taken to arrive at the truth, and we have no reason to doubt the accuracy of the statements contained in Mr. Clark's paper which was presented to the Massachusetts Board of Agriculture. But in our ignorance of the phenomena of plant life we should like to see the observations repeated. At the end of the experiment alluded to the soil was carefully washed from the roots of the pumpkin vine, and the entire system of roots spread out upon the floor of a large room and carefully measured. In addition to the main root, roots were formed at each joint or node. The total length of root developed was calculated to be over fifteen miles; and the time the plant was growing, four months. During the greater part of the time, of course, the rate of growth was relatively slow, but the maximum rate was computed at not less than one thousand feet of root per day.

With another plant of the same species, *Cucurbita maxima*, an experiment was instituted to ascertain the pressure exerted by the rising sap. For this purpose the plant was cut off near the ground, after it had attained a length of twelve feet, and a mercurial gauge attached to the part left in the ground. The maximum force with which the root of the pumpkin exuded the water absorbed by it was equal to a column of water 48·51 feet in height.

Some experiments to determine the channels through which the crude sap rises, and on the diffusion of the elaborated sap, gave interesting results. Mr. Clark says: "We find that the crude sap imbibed by the root-hairs from the surface of the particles of the soil seems to be taken up in a dry state; that is, it appears to be absorbed molecule by molecule, no fluid water being visible, and carried in this form through all the cellulose membranes between the earth and leaf, by which it is to be digested or exhaled. We do not say this is literally true, but it accords very nearly with what is constantly to be seen in some species of plants. The circulation of the sap in a poplar tree is very dry compared with that of the blood of any animal. Not a drop of moisture will ever flow from the wood of an aspen, so far as we have observed." It was found that an exceedingly small proportion of sap-wood sufficed to convey the necessary supply of crude sap to the foliage, but none would ascend through the bark.

The quantity of sap that flowed from different trees during the season varied greatly in diverse species. Thus the entire flow from the bitter-nut was less than the product of the sugar-maple for a single day; but the iron-wood and the birches surpass the maple in the rapidity and amount of their flowing. A paper-birch, fifteen inches in diameter, bled in less than two months over one thousand four hundred and eighty-six pounds of sap; the maximum flow, on the 5th of May, amounting to sixty-three pounds and four ounces. The grape bleeds comparatively little as compared with many other things. A very large proportion of the trees experimented upon did not show any tendency to bleed in spring. We might extract many other interesting details from Mr. Clark's paper, had we sufficient space for them.

PHYSICS IN GERMANY

(*From a German Correspondent.*)

HERR STEFAN, of Vienna, has published a paper on a series of researches on adhesion. It is well known that two plane plates which are placed upon one another adhere together so firmly that they can only be separated by a certain amount of force. This phenomenon has hitherto been considered as caused by adhesion (*i.e.* by the action of molecular forces between the particles in contact between the two plates), and it was tried to determine the magnitude of this adhesion statically.

The improbability of this conception already follows from the fact that in the case in question no immediate contact of the two plates takes place, but that between them there is a layer of air of considerable thickness. If two glass plates are employed for this experiment, they do not show Newton's coloured rings; these can only be produced with plates that are perfectly plane and with the application of considerable pressure. If, therefore, molecular forces were active in this case between the particles of the two plates, then the molecular sphere of action would have to be very much larger than is generally adopted according to other experiments. The phenomenon becomes still more striking if the experiment is made under water. In that case an attraction in the two plates can still be perceived, even if they are a millimetre apart. Herr Stefan used for his experiments two plates of glass, of which one was suspended from a balance in such a manner that its inferior plane was horizontal. The balance was then brought to equilibrium. The second plate was also placed horizontally under the other one. Three little pieces of wire were then placed upon it, and the upper plate was then let down so far as to rest upon these pieces of wire. By varying the thicknesses of the wires the distance of the two plates could be brought to any desired magnitude. To tear away the upper plate

from the under one, it was necessary to place a certain over-weight into the other scale of the balance.

It was found that the separation of the two plates can be accomplished by any force, however small, only the time in which the distance of the plates is increased by a certain fraction through the action of such a force, is all the greater, the smaller this force is. This time is still greater if the two plates are in water or in another liquid, instead of in air. To give an idea of this we may mention that the distance of two plates, of 155 millimetres diameter, under water, which originally was 0·1 mm., was increased in consequence of the continuous pull of 1 gramme by 0·01 mm. only in 1½ minutes, by 0·1 mm. only in 7 minutes.

Herr Stefan in his experiments measured the time that passed while the original distance of the plates increased by a certain fraction. First, the law was established for the motion of the plates in liquids as well as in air, that the times stand in the reverse proportion to the separating force. With the same overweight they are the longer, the smaller the original distance of the plates, but this in a far greater than a simple proportion; they increase nearly in square proportion if the distance of plates decreases in a simple one. For different sized plates the times in question stand in the proportion of the fourth powers of the semi-diameters of the plates; for different liquids in the same proportions as the times which elapse, while equal volumes of these liquids flow through a capillary tube, under equal pressure.

It results clearly that with this phenomenon there rests a problem of hydrodynamics and not of molecular forces. The phenomenon can be explained in the following manner:—When the separating force begins to act, the distance of the plates is increased by an infinitely small part. The space contained between the plates is thus enlarged, the liquid therein contained is dilated, and consequently its hydrostatic pressure decreased. The over-pressure of the exterior liquid acts against the separating force. No equilibrium is, however, attained, because the decrease of hydrostatic pressure between the plates causes an inflow of the exterior liquid and thus a decrease of the difference of pressure. The distance of plates may be again increased by the separating force, and then the same process is repeated in a continuous manner.

Herr Stefan has therefore given the name of *apparent adhesion* to this phenomenon. He has tried to deduce theoretically all the different laws to which the different experiments have led him; he has succeeded in finding an equation which expresses these laws, and which at the same time permits the deduction of the co-efficients of interior friction of the liquids experimented with, directly from the experiments. The values of the coefficients obtained in this manner correspond almost exactly with those obtained by the experiments of Poisseville, Maxwell, and O. E. Meyer. But as Herr Stefan thinks the theoretical solution of the problem only an approximate one, we reserve further details on the subject.

If we rub a wet cloth quickly over a glass tube, closed at both ends, it is caused to vibrate longitudinally. If at the same time it gives its lowest longitudinal note (as we will suppose for the sake of simplicity), then the end planes of the tube strike quite periodically against the air enclosed in it, and cause the same to vibrate. These vibrations are isochronous with those of the tube itself. They proceed from both ends of the tube towards one another, and, as a consequence, standing waves are formed in the enclosed air column. If into such a tube lycopodium or silicic acid has been placed, these powders (as also Herr Kundt has discovered a few years ago) collect at the node points of the standing waves and form figures of a very peculiar kind. As the length of these standing waves depends solely on the height of the generating sound and of the velocity of the waves in the gas, with which the tube is filled, the proportion of this wave-length to the wave-length in the glass gives the relative velocity of sound in air, with that in the glass as unity. Herren Kundt and Lehmann at Strasburg have lately tried to produce longitudinal vibrations and the figures just mentioned in a liquid, enclosed in a cylindrical tube, in a similar manner. It was found that in a column of water standing waves and figures can be produced almost as easily as in a column of air. The apparatus which was used for this purpose consisted of a glass tube, A B, closed at one end, B, which was placed firmly into a wider glass tube, C D, by means of an india-rubber stopper. The latter glass tube was closed at end D, and had two lateral outlets with stopcocks, so as to be easily filled with water. The powder which is placed in the tube C D must be sufficiently heavy and of a certain degree of fineness; it is best to use for this purpose finely divided iron (*Ferrum limatum*). The column of liquid must be free of even the smallest air-bubble. If the liquid used, for instance water, contains a gas absorbed, it must be first freed from it by continual boiling. In order to make the apparatus sound it is necessary only to rub a wet cloth quickly over the protruding part of the tube A B.

The figures in this column of liquid may serve for the determination of the velocity of sound in the liquid. If the end A of the sounding tube is closed by a cork, and if then over this end another tube is attached, which contains lycopodium, then, by the figures which occur in the liquid, and by those which occur in the tube with air, the wave-length of the same sound is obtained both in liquid and in air. The proportion of both gives the relative velocity of sound in the liquid with reference to that in air as unity. This relative velocity multiplied by the absolute velocity in air at the same temperature, gives the absolute velocity of sound in the liquid at the temperature in question. It was interesting to compare the results of this method of determining the velocity of sound in water, with the values required by the ordinary theory of the velocity of sound. According to the theory based on the experimentally determined elasticity of water, the velocity of sound at 8° Celsius is 1,437 metres. Colladon and Sturm, by their experiments in the Lake of Geneva, found the same to be 1,435 metres at 8° C. Although the remarkable coincidence of these values is only accidental, it is nevertheless proved that experiments such as those of Colladon and Sturm do not give figures that are very far from the theoretical values. The experiments of Kundt and Lehmann show that the diameter and thickness of the glass of the tube, which is used for the determination of the velocity of sound according to the method above described, greatly affect the value of the velocity of sound in water. In a tube of 2·2 mm. thickness of side, and 28·7 mm. diameter, the velocity at 18° C. was 1040·4 metres (the mean of two experiments which coincided very closely); in another one of 5 mm. thickness of side and 14 mm. diameter, the velocity was found 1382·2 metres at 22·2° C. As it would be very difficult to avoid unevenness in the sides of the tube, it does not seem probable that when using tubes the above value of 1,435 metres could be completely reached. These experiments, proving the influence of the thickness of the sides and diameter of a tube upon the velocity of sound in water, contradict the hypothesis of Wertheim, according to which a column of liquid, which is sounding or conducting sound, behaves like a firm rod,

S. W.

MAGNETO-ELECTRIC MACHINES *

FEW discoveries in physical science have been more important in themselves, or richer in practical results, than Faraday's discovery of the induction of electrical currents; and with the exception of the immortal work of Newton on the properties of Light, it would be difficult to mention any other experimental nvestigation, as it first issued from the hands of the author, so complete in all its details, or so full of new and original facts. Œrsted's grand discovery, which linked together electricity and magnetism, had already yielded a scientific harvest of uncommon richness. It led immediately to the construction of electro-magnets vastly exceeding in power any permanent magnets which were then known or have since been made. The multiplier or galvanometer of Schweigger supplied a new and important instrument for measuring electrical currents, which, with a little modification, became the electric telegraph. Faraday discovered the rotatory character of the reciprocal action of magnets and electrical currents; and Ampère showed that all the properties of a permanent magnet could be explained on the hypothesis of electrical currents in a fixed direction circulating around the magnet. A problem which proved to be one of surpassing difficulty, and long baffled many of the most distinguished physicists of Europe—to obtain electrical currents by means of a steel magnet—was in 1831 completely solved in the exhaustive memoir by Faraday, in which he announced the discovery of the induction of electrical currents. It may be interesting to describe, nearly in his own words, Faraday's original experiments.

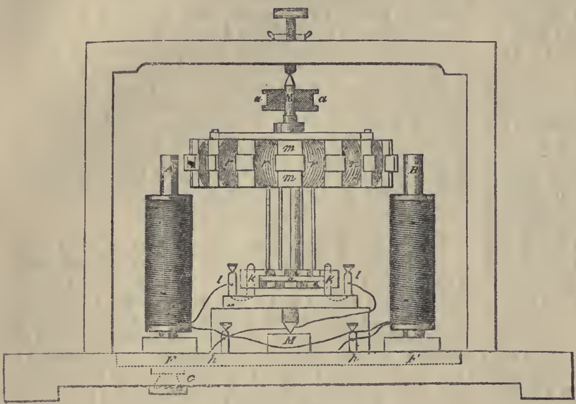

FIG. 1.—Pacinotti's Machine.

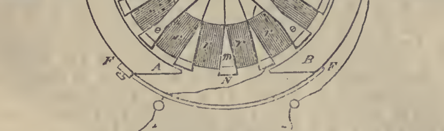

FIG. 2.—Pacinotti's Machine (Plan).

* The substance of a Lecture, with additions, delivered at the Belfast Philosophical Society, March 17, by Dr. Andrews, F.R.S., L. & E.

Two helices of insulated copper wire were passed round a wooden block, the ends of the wire of one helix being connected with a voltaic battery, and those of the other with a galvanometer. So long as the current from the battery passed through the first helix the needle of the galvanometer remained motionless, but on breaking the connection with the battery, a momentary current, as indicated by the galvanometer, traversed the wire of the second helix. The direction of this current was the same as that of the primary current of the battery. When the first helix was connected with the battery, another momentary current traversed the second helix, but in this case it was in the opposite direction to the primary current. Substituting for the first helix and the voltaic battery a permanent steel magnet or an electro-magnet, Faraday found that on introducing one end of the magnet into a hollow helix a temporary current was produced in the wire of the helix in one direction, and on withdrawing it another temporary current occurred in the opposite direction. For artificial magnets the magnetism of the earth may be substituted, and thus electrical currents can be obtained by induction from the magnetic conditions which everywhere prevail on the surface of this globe. The singular phenomenon first described by Arago, and afterwards elaborately investigated by Babbage and Herschel, that when a copper plate is rotated below a freely suspended magnet the latter tends to follow the motion of the plate, was shown by Faraday to arise from electrical currents induced by the magnet in the rotating metallic disc.

Soon after the announcement of these important results, Pixii constructed in Paris the first magneto-electric machine. I have still a vivid recollection of this machine as I saw it in Pixii's workshop. The currents were obtained by the rotation of a powerful horse-shoe magnet in front of an armature composed of two short bars of soft iron with a connecting crossbar, the latter being surrounded by a long coil of copper wire covered with silk. The armature had, in short, nearly the form of a horse-shoe electro-magnet. With this machine electrical sparks were obtained, and water was freely decomposed. In the rotation of the magnet the faces of the armature or electro-magnet became successively north and south poles with intermediate conditions of neutrality, and the direction of the current changed at every semi-revolution of the magnet. Hence, in the decomposition of water and other electrolytes, the ele-

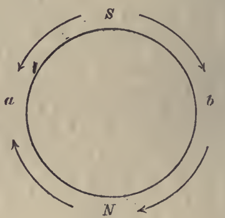

FIG. 3.

ments or radicles produced by the electrolysis could not be obtained separately. Pixii is said to have applied a commutator to his machine in order to obviate this defect. An important modification of Pixii's machine was soon after made by Paxton, who caused the armature to revolve instead of the permanent magnet. According to the character of the current required, armatures with longer or shorter wires were employed. A large machine of this construction, exhibited some years ago at the Polytechnic Institution in London, was capable of igniting a short platinum wire. In Clarke's machine the position of the armature was altered and an improved commutator applied. Siemens afterwards, by giving the armature a cylindrical form, rendered it more compact and better fitted for rapid rotation.

Siemens' armature was happily applied by Wilde, in 1866, to the construction of a machine of extraordinary power. Starting from a small magneto-electric machine provided with six steel magnets, each weighing one pound, and capable of carrying about ten times their weight, Wilde transmitted the direct current from this machine through the coils of an electro-magnet provided like the former with a Siemens' armature, and the direct current from the latter he in like manner transmitted through the coils of another large electro-magnet—so large, indeed, that its armature alone weighed above one third of a ton. This was also provided with a Siemens' armature. When the machine was in full action it melted a rod of iron 15 inches in length and a quarter of an inch in diameter, and gave the most brilliant illuminating effects when the discharge took place between carbon points. As nearly as could be estimated, the mechanical force absorbed in producing these results was from eight to ten-horse power. Wilde's machines have been successfully employed by Messrs. Elkington for the precipitation of copper and other metals, and he has lately proposed some important modifications to adapt them to the production of the electric light.

Some years before Wilde's experiments were published, Holmes had constructed on the Saxton principle a powerful magneto-electric machine, which has been successfully used at Dungeness and other lighthouses, and machines differing little from Holmes's are employed in some of the French lighthouses. In Holmes's original machine forty-eight pairs of compound bar-magnets were arranged for the armatures (160 in number) to revolve between the poles of the magnets, and by a system of commutators the current was obtained always in the same direction. Its amount, however, varied at almost indefinitely short intervals from a maximum to one-half of that amount. In practice these variations were wholly inappreciable.

The first suggestion of a magneto-electric machine capable of giving a continuous current always in the same direction is due to Dr. A. Pacinotti, of Florence. In the nineteenth volume of "Il Nuovo Cimento," which was published in 1865,* Pacinotti describes the model of an electro-magnetic machine constructed, some time before, under his direction, for the Cabinet of Technological Physics in the University of Pisa, whose essential feature was a novel form of armature to which he gave the name of "transversal electro-magnet." This armature was formed of a toothed iron ring, *m m* (Fig. 1), capable of rotating on a vertical axis, M M, and having the spaces between the teeth occupied by helices of copper wire covered with silk. The wire of the helices was always wound in the same direction round the ring, and the terminal end of each helix was brought into metallic connection with the adjoining end of the wire of the succeeding helix. From these junctions connecting wires were carried down parallel to the axis of the machine, and united to insulated plates of brass, of which a double row, as shown in Fig. 1, were inserted in a wooden cylinder, *c*, which was itself firmly attached to the lower part of the axis. The current entered through the successive brass plates as they came into contact with a small metallic roller, *k*, which was in communication with one pole of a voltaic battery. At the point of junction with the wires of the helices, the current from the battery divided into two parts, which respectively traversed in opposite directions the connected helices, each through a semi-diameter of the ring, and finally left the machine on the opposite side by a second roller, *k*, which was in connection with the other pole of the battery. When the connections were made, the iron ring began to rotate round its axis with considerable force. In a trial in which the current was supplied by four small elements of Bunsen, a weight of several kilogrammes was raised. In the apparatus as actually constructed, the poles of the electro-magnet were enlarged by the addition of two segments of soft iron, A A, B B (Fig. 2), which extended over the greater part of the iron ring. The details of the construction of the transversal electro-magnet will be easily understood from the plan given in Fig. 2.

Towards the end of the paper to which I have already referred, Pacinotti shows that the iron ring armature, or transversal electro-magnet, may be applied to reverse the conditions just described, and to obtain continuous electrical currents, always in the same direction, from a magnet, whether a permanent one, or an electro-magnet. As the original paper has not, as far as I know, been translated into English, and the scientific journal in which it was published is little known in this country, I will not make any apology for giving the following extract without abridgment.

"If we substitute for the electro-magnet A B (Fig. 1) a permanent magnet, and make the transversal electro-magnet revolve, we shall have a magneto-electric machine which will give an induced continuous current always in the same direction. To find the most suitable positions on the commutator from which to collect the induced current, let us observe that in presence of the poles of the fixed magnet, there are formed, by influence, at the extremities of a diameter, opposite poles on the moveable electro-magnet. These poles, N S (Fig. 2), maintain a fixed position when the transversal electro-magnet rotates upon its axis; and therefore, in respect to the magnetism and consequently to the induced currents, we may consider, or suppose, that the helices of copper wire move round on the ring magnet while the ring itself remains at rest. To study the induced currents which are developed in these helices, let us take one of them in the various positions it can assume. From the pole N (Fig. 3) advancing towards the pole S, there will be developed a direct current in one direction till the middle point *a* is reached; on passing this point the current will assume an opposite direction. Proceeding from S towards N, the current will maintain the same direction which it had from *a* to S, till the middle point *b* is reached; after passing *b* the direction will be again changed, and will now be the same which it had from N to *a*. Now, since all the helices communicate with one another, the electro-motive forces will be collected in one given direction, and will give to the entire current the course indicated by the arrows in Fig. 3;* and for collecting it, the most suitable positions will be *a b*; that is to say, the rollers on the commutator should be placed at right angles with the line of magnetism of the electro-magnet."

Pacinotti does not appear to have constructed specially a magneto-electric machine on the above principle, but he states that he verified the correctness of his views by turning the iron ring in the electro-magnetic machine, and observing the direction of the currents when a galvanometer was introduced into the circuit.

* The date on the title-page of the volume is 1863, but it contains a letter dated Rome, Jan. 19, 1865

* Fig. 3, as given in the text, is an exact fac-simile of the corresponding figure in the original. It is obvious from the figure itself, as well as from the text, that there is an error in the engraving, and that the arrow between S and *b* should point towards S and not towards *b*.

The results he obtained were not great, but were sufficient to enable him to announce that a magneto-electric machine could be constructed which would have the advantage of giving the induced currents all in the same direction, without the help of mechanical arrangements to separate opposed currents or to make them conspire with one another.

From the foregoing analysis of Pacinotti's memoir, there can be no doubt that it contains a description of the ring armature which in the hands of Gramme has recently led to the construction of magneto-electric machines giving continuous currents of great intensity. I cannot, however, pass over without notice an extraordinary blunder into which Pacinotti has fallen, and which would render any machine constructed after his model altogether valueless. By a reference to Fig. 2, which, as well as Figs. 1 and 3, has been engraved from a photograph of the plate appended to the original memoir, it will be seen that the letters N and S are placed at the end of the diameter of the ring which is at right angles to the line A B joining the poles of the fixed magnet. That Pacinotti intended these letters to designate north and south magnetic poles is manifest from the following passage among others in his memoir:—"Osserviamo che per influenza sulla elettro-calamita mobile si formano i poli opposti alle estremità di un diametro in presenza ai poli della calamita fissa. *Questi poli* N S mantengono una posizione fissa anche quando la elettro-calamita trasversale ruota sul suo asse." It is hardly necessary to say that the positions assigned by Pacinotti for the poles in an iron ring under the influence of a fixed magnet are in reality those of the neutral points, or points of no magnetism, and that the magnetic poles of the ring are at a distance of 90° from the positions stated by him. This mistake has led to a serious blunder in the construction of his machine, the metallic rollers which carry off the induced currents being placed, not at the neutral points (as Pacinotti has himself clearly showed that they ought to be), but at the poles of the ring. That any effects at all were obtained from the model at Pisa, we must attribute to the slight shifting of the poles of the ring due to its rotation. Apart, however, from this unaccountable error, it can scarcely be disputed that to Pacinotti is due the merit not only of having devised the ring armature or transversal electro-magnet, but of having also accurately analysed its mode of action.

(*To be continued.*)

*LECTURES AT THE ZOOLOGICAL GARDENS**

V.

Mr. Garrod on Camels and Llamas

THE Tylopoda form a group which includes the Camels together with the Llamas; the name indicating that their feet are covered with callous skin instead of with hoofs as in the typical Ruminants, from which group they also differ considerably in many other characters, to be considered seriatim.

Horns are not developed in either sex. The upper lip is hairy and partly cleft. False hoofs are wanting. The general body-proportions are not so symmetrical as in any of the Cavicornia or Deer. Osteologically several special features present themselves. In the vertebræ of the neck the canals which are developed in the transverse processes, for the vertebral arteries to run in on their way to the brain, are excavated in the sides of the spinal canal of the cervical region. In the ankle two of the bones—the naviculare, or scaphoid, and the cuboid—which are anchylosed in the true Ruminants, are independent of one another. In the upper jaw there are two teeth developed, one on the side of each premaxilla; they are therefore lateral incisors. The canines in the lower jaw are of a different shape, and are separated by an interval from the incisors. The molars form a series of five above and four below; in the Camels, but not in the Llamas, an additional small premolar, isolated in position and following the canine, is to be found in both jaws, increasing the grinder series to six above and five below on each side.

* Continued from p. 69.

The abnormal conformation of the gastric section of the alimentary canal in the Camels has attracted the attention of many naturalists. In the Llamas the same structure maintains. As in the typical Ruminants the stomach is composed of several cavities communicating one with the other, but there is some difficulty in deciding which are the exact homologues of the *rumen*, *reticulum*, *psalterium*, and *abomasum*. The first cavity is a capacious globose sac into which the œsophagus opens. A longitudinal band of muscular fibre partly constricts it, in its course from the right side of the cardiac orifice backwards along the ventral surface, opposite the middle of which a narrow and long aggregation of "water cells" starts to continue tranversely towards the left side of the organ. This longitudinal muscular band forms one of the boundaries—the left one—of a much larger collection of deeper water cells, which embrace the posterior portion of the right side of the paunch in the concavity of their crescentic mass. From the right of this first main compartment a second smaller one is cut off by a constriction which leaves a considerable opening between the two. Its position is that of the reticulum; it is deeply honeycombed, the lining membrane of the cells being covered with villi much like those on the surface of the folds of the psalterium of the deer, &c. The cell-walls are thin and but slightly muscular. In the paunch the mucous membrane is smooth and not at all thick. The water-cells are formed on a framework of many intersecting muscular sheets arranged in layers with intervals of less than an inch between them, one half being at right angles to the other, so as to form rows of quadrilateral cavities. These are again incompletely divided up by secondary septa. The orifices of the cells are partly closed by diaphragm-like membranes at their mouths. Most probably the contraction of the aggregated muscular fibres in the same situations is capable of closing the cells completely when necessary. That the camel can store fluid in these water-cells is borne out by the experience of so many authors that doubt is scarcely possible. For instance, in his "Travels to discover the Source of the Nile," Bruce (vol. iv. p. 596) tells us on one occasion that "finding the camels would not rise, we killed two of them . . . and from the stomach of each got about four gallons of water, which the Bischareen Arab managed with great dexterity." As John Hunter remarks, there is no physiological reason why this should not be the case. A specialised structure is observed by zoologists; a special power is attributed by travellers; the function and the structure may be reasonably correlated: why should they not be so, as no other explanation suggests itself? There is no arrangement for closing the cells of the reticulum similar to that found in those of the rumen.

A muscular fold runs from the termination of the œsophagus along the superior or vertebral side of the lesser curvature of the stomach to the third compartment, which evidently directs the products of rumination into it, just as the two folds of the same region do which traverse the reticulum in the typical Peccora. Following the honeycomb-bag is a single elongate cylindrical cavity, which dilates slightly and becomes bent at its pyloric extremity. This compartment is thin-walled and longitudinally ribbed internally for its proximal five-sixths, beyond which the mucous membrane is much thickened and evidently digestive in character, especially in the neighbourhood of the angle of the inflection in that region. This section of the stomach apparently corresponds to

the abomasum, the psalterium being absent. In the Bactrian Camel there is a partial constriction in it, which separates off a small proximal cavity, which may be its homologue.

In the corpuscles of the blood the Tylopoda are unique among Mammalia, these minute discs being oval instead of, as in all other members of the class, circular.

Of the Camels there are two species, both domesticated, the Bactrian and the Arabian; the one possessing two humps and the other one. A swift variety of the latter is called the Dromedary. The former inhabits Turkestan, Persia, Thibet, and Mongolia; the latter Arabia and Northern Africa. Of the Llamas there are two wild species which have each of them domesticated representatives; the feral Guanaco and Vicuna finding their tame representatives in the Llama and Alpaca. They are all found in the Cordilleras of the Andes, down as far as Terra del Fuego. Taking the Tylopoda as a whole, their geographic range is extremely exceptional. Closely allied animals, as the Ostrich and the Rhea, are found in South Africa and South America respectively. North Africa and Arabia, in some respects, resemble India, as far as their fauna is concerned. No similar ties bind Northern Africa with South America, and it is this which makes the distribution of the Camels and Llamas so abnormal and so inexplicable, on the assumption that they sprang from a common ancestor as far back as the Miocene age, when we take as our basis the assumption that the existing zoological regions are the remains of a very different distribution of land.

(*To be continued.*)

THE LINE BETWEEN HIGHLANDS AND LOWLANDS

THE usual ten days' excursion which terminates the work of the Geological Class at the University of Edinburgh, has this year been devoted to an experiment in the practical teaching of Geology which bids fair to be often and profitably repeated—viz., the working out of a definite problem in the field, teacher and students together. In the Class excursion to Arran in 1872, it was observed that the Old Red Sandstone appeared to be brought against the Highland schists by a fault. Last year the fault was actually seen by the Class on the other side of the island in the cliffs of Stonehaven. Accordingly, the task proposed to be accomplished this year was to trace this dislocation across the country, if possible, from sea to sea. Such a traverse would at least bring the pedestrians face to face with some of the finest and least visited river scenery in Scotland, while it would probably also impress some geological lessons on their memory in a way not likely ever to be forgotten. At the same time it might be successful in discovering some new points in British geology.

The party mustered at Edinburgh, and proceeded at once to Stonehaven, where the first day's work consisted in following the magnificent coast-section which rises above the sea in the picturesque cliffs of Kincardineshire. The fault by which the slates and greywackes of the Highlands have been brought side by side with the red sandstones and shales of the Lowlands was again found. The rocks have there been so greatly squeezed against each other that their line of separation is by no means so abrupt as it might be expected to be. Instead of the mass of débris which so often fills up the space between the cheeks of a large dislocation, there was in this case a somewhat tortuous line of junction along which, without any broken materials intervening, the two series of Highland and Lowland rocks seemed to be, as it were, welded together. One might pass this part of the section and fail to notice the fault, though at the distance of a few yards he would find himself in a totally different set of rocks, and would then turn back to discover the actual line of separation. That this fault must be an inportant one was first shown by the fact that the strata of the Old Red Sandstone have here been thrown on end for more than two miles back from their junction with the Highland rocks. Along the noble coast cliffs the beds of sandstone and conglomerate stand on edge like books on the shelves of a library. The portion of them so placed considerably exceeds 10,000 feet in thickness, and yet by no means includes all the Old Red Sandstone of this part of Scotland.

From Stonehaven the party worked its way across the country for more than 100 miles to the Aberfoyle district. The line of junction between the slates and the Old Red Conglomerates and Sandstones was traced at many points, and sometimes followed for miles across the moors. In no case was the actual fault again seen, but its position could be in most cases drawn firmly on the map by help of the numerous sections laid open by the rivers which descend from the south-eastern slopes of the Grampians. As the journey advanced, however, it was discovered that the fault did not always lie between the Highland rocks and the Old Red Sandstone, but that it sometimes left bays of the latter formation on its north side. This was a new and interesting fact, for it showed the base of the Old Red Sandstone of these regions lying undisturbed and unconformably upon the upturned edges of the slates. In these bays were found enormous beds of coarse volcanic conglomerate and sheets of porphyrite, precisely agreeing with those which form the chains of the Ochil and Sidlaw Hills on the south side of the great valley which here flanks the Highlands. It was, therefore, apparent that the lavas, ashes, and gravels originally extended quite up to and enveloped the base of the Highland mountains that bounded on the north the inland sea or lake in which the Old Red Sandstone was deposited.

But perhaps the question of most general interest elucidated by this excursion was the relation between lines of dislocation and lines of valley. The fault which begins on the east coast at Stonehaven and runs in a straight line across the country to Arran—a distance of 170 miles—is probably one of the greatest, if indeed it is not absolutely the greatest, in Britain. We do not yet know the amount of displacement which it has caused. But that it was accompanied by enormous movement of the earth's crust is sufficiently proved by the band of vertical strata, sometimes more than two miles broad, which runs along its southern border. Surely if the valleys and gorges of this country, as many writers still contend, have been caused by or are coincident with lines of subterranean fracture, such a grand line of fracture as this ought to be strikingly characterised by such surface features. Particular attention was devoted to this point during the excursion, and the result may be briefly given. Not a single main valley was found to run along the fault, while all the valleys and some of the deep gorges emerging from the Highlands run directly across it without deflection. In one case only was there an approach to a coincidence between the line of the fault and a glen, viz., in that of Glen Artney. But there the dislocation, instead of keeping the centre of the valley, was found to run far up on the northern side, the stream in the centre winding to and fro across the vertical strata of Old Red Sandstone. Along its whole course the fault is not more marked than on other lines where two series of rocks of different characters and modes of weathering come together. But not only does no long and broad valley or series of valleys mark the line of this fracture in its passage across the island; it passes athwart the channels of the North and South Esk, the Prosen, the Isla, the Ericht, the Tay, and the Forth, without in the least degree producing any waterfalls or transverse gorges. Moreover, it cuts across two of the best known lakes of

the Southern Highlands, Lochs Vennachar and Lomond, without revealing its presence by any abrupt surface features. These transverse valleys can be admirably studied in some of the river ravines. The gorges of the Ericht, Isla, and North Esk, indeed, are true cañons, their precipitous walls range from 80 to sometimes 200 feet in height, between which the rivers toil in narrow tortuous chasms. It is easy to examine the strata in these natural sections, and to find conclusive proof that in spite of their fissure-like character the ravines have been cut out of the solid and unbroken Old Red Sandstone, the strata of which can be traced from side to side in undisturbed continuity. The pot-holes marking old levels of water-grinding can be traced at various heights above the present streams, which are still at work deepening their channels in the same way. The contribution therefore which this geological ramble makes to the discussion of an interesting question in the physiography of Great Britain may be put thus:—An enormous dislocation crosses the island along the southern margin of the Highlands. It has not given rise to any marked line of glens or valleys. It is crossed by all the rivers and some of the lakes which emerge from the southern side of the Grampians, and some of these rivers flow in deep narrow gorges across the line of fracture. Yet in none of these gorges could any trace be found of transverse fracture; on the contrary, they everywhere bore evidence only of long-continued aqueous erosion.

Another point of interest noted in the course of the excursion was the fact that Comrie—a locality so long and widely celebrated for its frequent and sometimes sharp earthquake shocks—lies almost directly over the line of the great fault. This fact seems to be the first of any consequence which has been ascertained in the attempt to connect the abundance of tremors at that place with any geological structure of the ground underneath. From this brief notice it will be seen that there was plenty of geological interest and novelty to keep up the enthusiasm of the party from the beginning to the close of the excursion. Glorious weather and an endless variety of scenery added fresh charms to each day's work, while over the whole came the glee and hearty exuberance which the free open face of nature could not but evoke in men who had been working hard together in town all the winter and spring.

THE U.S. GOVERNMENT BOARD FOR TESTING IRON AND STEEL

IN accordance with "An Act making Appropriations for Sundry Civil Expenses of the Government, for the fiscal year ending June 30, 1876, and for other purposes," approved March 3, 1875, and in reply to a memorial presented to Congress in January last by the American Society of Civil Engineers, the President of the United States has appointed a Board with instructions to determine by actual tests the strength and value of all kinds of iron, steel, and other metals which may be submitted to or procured by it, and to prepare tables which will exhibit the strength and value of these materials for constructive purposes.

The object of this Board is so admirable, and in this, as already in some other similar respects, the U.S. has set an example so worthy of imitation by European Governments, that we shall be doing a service in publishing the details of the organisation of the Board. Congress, we may state, has voted 50,000 dollars to defray the expenses of the Board.

The following are the names of its members:—President, Lieut.-Col. T. T. S. Laidley, U.S.A.; Commander L. A. Beardslee, U. S. N.; Lieut.-Col. Q. A. Gillmore, U. S. A.; Chief Engineer David Smith, U. S. N.; W. Sooy Smith, C.E.; A. L. Holley, C.E.; R. H. Thurston, C.E., Secretary.

The work of the Board is divided into sections, each section being entrusted to a standing committee from the members of the Board. The following are the Sections:—

(A) *On Abrasion and Wear.*—Instructions: To examine and report upon the abrasion and wear of railway wheels, axles, rails, and other materials, under the conditions of actual use.

(B) *On Armour Plate.*—Instructions: To make tests of armour plate, and to collect data derived from experiments already made to determine the characteristics of metal suitable for such use.

(C) *On Chemical Research.*—Instructions: To plan and conduct investigations of the mutual relations of the chemical and mechanical properties of metals.

(D) *On Chains and Wire Ropes.*—Instructions: To determine the character of iron best adapted for chain cables, the best form and proportions of link, and the qualities of metal used in the manufacture of iron and steel wire rope.

(E) *On Corrosion of Metals.*—Instructions: To investigate the subject of the corrosion of metals under the conditions of actual use.

(F) *On the Effects of Temperature.*—Instructions: To investigate the effects of variations of temperature upon the strength and other qualities of iron, steel, and other metals.

(G) *On Girders and Columns.*—Instructions: To arrange and conduct experiments to determine the laws of resistance of beams, girders, and columns to change of form and to fracture.

(H) *On Iron, Malleable.*—Instructions: To examine and report upon the mechanical and physical proportions of wrought iron.

(I) *On Iron, Cast.*—Instructions: To consider and report upon the mechanical and physical properties of cast iron.

(J) *On Metallic Alloys.*—Instructions: To assume charge of a series of experiments on the characteristics of alloys, and an investigation of the laws of combination.

(K) *On Orthogonal Simultaneous Strains.*—Instructions: To plan and conduct a series of experiments on simultaneous orthogonal strains, with a view to the determination of laws.

(L) *On Physical Phenomena.*—Instructions: To make a special investigation of the physical phenomena accompanying the distortion and rupture of materials.

(M) *On Re-heating and Re-rolling.*—Instructions: To observe and to experiment upon the effects of re-heating, re-rolling, or otherwise re-working; of hammering, as compared with rolling, and of annealing the metals.

(N) *On Steels produced by Modern Processes.*—Instructions: To investigate the constitution and characteristics of steels made by the Bessemer, open hearth, and other modern methods.

(O) *On Steels for Tools.*—Instructions: To determine the constitution and characteristics, and the special adaptations of steels used for tools.

The Sectional Committees of the Board, we learn from the official circular sent us, are appointed to conduct the several investigations, and the special researches assigned them in the interval during which the regular work of the Board is delayed by the preparation of the necessary testing machinery, and during such periods of leisure as may afterward occur.

These investigations are expected to be made with critical and scientific accuracy, and will, therefore, consist in the minute analysis of a somewhat limited number of specimens and the precise determination of mechanical and physical properties, with a view to the detection and enunciation of the laws connecting them with the phenomena of resistance to flexure, distortion, and rupture.

The Board will be prepared to enter upon a more general investigation, testing such specimens as may be

forwarded to the President of the Board, or such as it may be determined to purchase in open market, immediately upon the completion of the apparatus ordered, at which time circulars will be published giving detailed instructions relative to the preparation of specimens for test, and stating minutely the information which will be demanded previous to their acceptance.

GUSTAVE THURET

ON the 10th of May France lost one of her most distinguished naturalists. M. Thuret left his home at Antibes in perfect health, and expired at Nice a few hours afterwards from an attack of angina pectoris.

Unlike many of his contemporaries, Thuret was not a voluminous writer. But his papers, though not numerous, are all extremely admirable, and his work has laid the foundation of our modern knowledge of the biological phenomena of the Algæ. Probably his earliest paper was an account of the antherozoids of *Chara* (1840). He was the first to detect the cilia upon these structures in any plant. In 1844 he published an account of the peculiar mode of asexual reproduction in *Nostoc*. In 1845, in conjunction with Decaisne, he described for the first time the antheridia and antherozoids of *Fucus*. In 1850 and succeeding years he published his admirable papers upon the zoospores of different groups of Algæ. In 1853 he established for the first time by actual observation, in the case of *Fucus*, the existence amongst Algæ of the phenomenon of fertilisation. In 1866, in conjunction with Bornet, he described the extremely remarkable phenomena of sexual reproduction amongst the *Florideæ*. They found not merely that the process of fertilisation was accomplished in a very peculiar and remote way, but also that, besides the effect produced on the germ-cell, a series of developments were induced in the parent plant as the result of it. In every group of Algæ the results which he achieved were of the most fundamental kind.

A man of independent wealth, he passed a great part of the year on his property at Antibes, on the shore of the Mediterranean. Bornet, his distinguished *collaborateur*, lived with him. In the gardens which surrounded his house he had assembled one of the most remarkable collections of plants to be found growing in the open air in any part of the world. W. T. T. D.

NOTES

PUNCTUALLY at the time arranged, four o'clock in the afternoon of last Saturday, the *Alert* and the *Discovery*, accompanied by the *Valorous*, left Portsmouth for their work in the Arctic regions. No better equipped expedition, it may again be said, has ever left any country, and no previous British expedition has ever been so universally popular. Every available point on land was occupied by spectators who had come to see the departure of the expedition. The vessels in the harbour and the yachts and boats along the beach were dressed with flags, and as the two ships stood out to sea their course lay through a perfect flotilla of craft of all kinds, whose occupants cheered Capt. Nares and his companions on their way. Among the last messages received by Capt. Nares was a telegram from the Queen "wishing you and your gallant companions every success;" the telegram was accompanied by a packet, the contents of which did not transpire. In the morning the Lords of the Admiralty inspected the ships, and wished the expedition "God speed." Mr. Clements R. Markham accompanies his cousin, Commander Markham, as far as Disco. The sbips arrived at Queenstown on Tuesday, the *Alert* and *Discovery* going on to Bantry Bay. The *Valorous* joined them yesterday, when the three proceeded on their way.

MR. GEORGE BENTHAM, F.R.S., has been elected a corresponding member of the French Academy of Sciences.

MR. CHARLES DARWIN has been appointed foreign honorary member of the Imperial Academy of Science, Vienna.

THE Hebdomadal Council of Oxford University have agreed to propose that in the Convocation to be held at the Encœnia, or Commemoration, the honorary degree of D.C.L. be conferred on the following persons:—Sir W. R. Grove, F.R.S., Sir J. Lubbock, F.R.S., Mr. E. B. Tylor, F.R.S., Captain Douglas Galton, C.E., F.R.S., and Mr. C. T. Newton.

THE reception at the Royal Society on Wednesday week was a great success; there was a very large attendance of Fellows. There was plenty of opportunity for quiet talk, which was taken ample advantage of. Mr. Crookes repeated his interesting experiments.

GOVERNMENT have refused to send or pay the expenses of a commissioner to the forthcoming International Geographical Congress at Paris. One would have thought that, as much from a practically commercial as from a scientific point of view, this Congress, judging from its programme, is likely to be of the highest importance; and who more likely to reap benefit from such a Conference than the greatest naval and commercial power in the world? Government, however, have the excuse that the French Government simply approve of the Congress, and have refrained from stamping it with an official character.

INVITATION circulars have been issued for the Bristol Meeting by the British Association, whose sittings commence on August 25, under the presidency of Sir John Hawkshaw, C.E., F.R.S. The local secretaries are Messrs. W. Lant Carpenter and John H. Clarke.

M. EDOUARD COLLOMB, who for many years has been the Treasurer of the Geological Society of Paris, has just passed away at the age of seventy-four years. M. Collomb accompanied Agassiz in his Alpine travels. He also travelled during many years in Spain with M. de Verneuil, studying the mineralogical resources of the Iberian Peninsula. The result of these protracted explorations was the publication of the first geological map of Spain.

MR. HENRY WILLETT again appeals for funds to carry on the work of the Sub-Wealden Exploration to a depth of 2,000 feet. A week ago the boring had reached 1,080 feet. It has been decided to continue the boring to 1,500 feet, by which time all the available funds will be exhausted; to do this, 1,200*l*. are wanted, and we cannot think that for the want of so comparatively small a sum the first scientific boring in this country will be brought to a premature conclusion. The latest cones and fossils indicate that the boring is still in the Kimmeridge Clay, to the fauna of which *Ammonites Jason* must now be added.

THE acclimatisation of trout in Tasmania is certified by an official report, which states that in 1873 a total distribution of 4050 trout ova was made from the rivers of that country to the neighbouring colonies; 800 of these ova were sea trout, and the rest brown trout.

THE motion for diminishing the size of the type used in printing the *Comptes Rendus* was lost, because a number of members declared in the private sitting of the Academy that it was impossible for them to read the papers printed with the characters which had been proposed. Consequently it has been resolved that the number of pages given to each paper shall be diminished by one-third part of the number originally allotted.

THE Municipal Council of Paris have voted a sum of 500*l*. to pay the professors of a superior school of Anthropology, which will be opened next November in a building lent gratuitously

by the École de Médecine; no fees are to be charged from pupils. M. Wallon has granted a sum of 300*l.* yearly for laboratory expenses. Anthropological societies and private individuals have subscribed a fund; the shares are said to be worth 40*l.* Five courses of lectures are to be delivered, including a series by M. Broca on Craniology, by M. Dailly on Human Races, M. G. de Mortillet on Prehistoric Times. The number of lectures is to be increased as the resources of the association multiply.

ACTIVE preparations are being made for the exhibition of the French Geographical Society at the Pavillon des Flores. The large hall is almost finished, and is said to be of superior taste and magnificence.

FOR the first time in recent years the French Minister of Public Instruction is one of the leading members of the Cabinet. It is said that in the discussion on the new electoral law, M. Wallon intends to ask the Versailles Assembly to vote that ignorance be considered a disqualification, and that any elector be disfranchised who cannot read and write.

M. GEOFFROY SAINT-HILAIRE, the Director of the Jardin d'Acclimatation, Paris, has just instituted a new intermediate station for tropical plants at the Iles d'Hyères. Delicate plants will consequently not be taken at once from a hot to a cold atmosphere.

A MEMORIAL tablet, bearing an appropriate inscription, now marks the spot in Westminster Abbey where the remains of Dr. Livingstone are deposited.

A SCIENTIFIC Society has recently been established in Caius College, Cambridge, for the diffusion of scientific knowledge among the members of the College, for the reading of essays on scientific subjects, and for the holding of scientific discussions. The Society admits within the range of its discussions all sciences of observation. An interesting feature in the scheme of the Society's proceedings is that the first half-hour of each meeting is to be devoted to open discussion, to the answering of questions proposed by any member either at the time or at a previous meeting, or to the exhibition of specimens. The first president of the Society is Mr. B. Anningson, M.A., M.B., the newly-appointed Medical Officer of Health for Cambridge, and the secretary is Mr. Wm. Ewart. A number of papers have been read during the present term. The meetings have been well attended and the discussions well supported.

A SCIENTIFIC Society has been formed at Gloucester, chiefly in connection with the School of Science there, under the title of the Gloucester Philosophical Society. A programme of papers for the year has been issued. In addition to the regular monthly meetings, a course of six lectures on Structural Botany is being delivered by Mr. Allen Harker to the members of the Society. One or more excursions are to form a feature of the course. Gloucester has hitherto been rather apathetic than otherwise on science; this looks more healthy.

ON Nov. 23, at Balliol College, Oxford, there will be an examination for a Brackenbury Scholarship for the encouragement of Natural Science, worth 80*l.* a year for four years.

WE are very much surprised, and on all accounts it is greatly to be regretted, that the Legislature of Massachusetts has rejected the Bill for a new Survey of the State to which we have already referred. Massachusetts is known all the world over as being one of the most intelligent and best educated States in the Union. Evidently, however, the State schools are too strong in arithmetic; a Mr. Plunkett brought some extraordinary calculations before the House, showing that the Survey would cost nearly a million and a half of dollars and occupy nearly a hundred years! Besides an advanced and accomplished calculator, the Massachusetts Legislature is also happy in the possession of a "funny man," a Mr. Rice, who seems occasionally to relieve the severity of Mr. Plunkett's extreme calculations by bright flashes of buffoonery. Mr. Rice described the proposed Survey as "sending young men with muck-rakes to scratch the sterile soil of the State and make pictures."

THE Indian Museum at South Kensington was opened to the public on the 1st instant.

THE newly issued part of the Transactions of the Zoological Society of London contains an exhaustive memoir on the birds inhabiting the Philippine Archipelago, illustrated by twelve coloured quarto plates.

PROF. HALL GLADSTONE completed his course of lectures at the Royal Institution on chemical force on Tuesday, and exhibited a new compound he had just discovered, Zinc Ethylochloride, $Zn\left\{\begin{matrix}C_2H_5.\\Cl\end{matrix}\right\}$

THE necessity of utilising the large rivers for maritime navigation is becoming one of the questions of the day in France. The Municipal Councils of Lyons and Marseilles are considering the means of connecting Marseilles with the Rhône by a canal practicable for shipping; while the Municipal Council of Paris have appointed a commission to devise means to render the Seine navigable from Rouen to Paris.

PROF. DRAKE, the eminent Berlin sculptor, has just finished a colossal statue of Alexander von Humboldt, ordered by the city of Philadelphia; it is nine feet high, and will be shipped to its destination early in June.

A TELEGRAM, dated Berlin, May 28, states that the Tashkend Government has sent an expedition to Hissar, an unknown principality east of Shahrisiabsk, and north of the Afghan frontier. The members of the expedition are mostly scientific.

BAILLIÈRE, of Paris, has published an analytical "Table des Matières" of the first ten volumes (1864-74) of the *Revue Scientifique*. The Table forms a very useful index to much of the scientific work of the last ten years.

A THICK Supplement (No. 41) to *Petermann's Mittheilungen* has just been published, containing a multitude of statistics on the population of the earth, by E. Behm and H. Wagner. They estimate the total population of the globe at 1,396,842,000, distributed as follows:—Europe, 302,973,000; Asia, 798,907,000; Africa, 206,007,000; America, 84,392,000; Australia and Polynesia, 4,563,000.

HEFT VI. of *Petermann's Mittheilungen* contains a beautiful map illustrative of Dr. Rohlfs' travels in the Libyan Desert during 1873–74. It embraces the portion of North Africa between 25° and 29° N. lat., and 26° and 32° E. long. This map, along with the explanatory letterpress by Dr. Jordan and Dr. Rohlfs which accompanies it, will be found to add in a very important degree to an accurate knowledge of this hitherto imperfectly known region. The map shows the route not only of Rohlfs' expedition, but of Schweinfurth and several other explorers, from Krump (1701) downwards.

IN a paper by Prof. J. D. Dana, in the May number of Silliman's *American Journal*, on Dr. Koch's evidence with regard to the contemporaneity of Man and the Mastodon in Missouri, the author comes to the following conclusions:—Taking all things that have been reviewed into consideration, he thinks there is sufficient reason for regarding Dr. Koch's evidence of the contemporaneity of Man and the Mastodon *very doubtful*. He hopes that the geologists of the Missouri Geological Survey now in progress will succeed in settling the question positively. The contemporaneity claimed will probably be shown to be true for North America by future discoveries, if not already so esta-

blished; for Man existed in Europe long before the extinction of the American Mastodon.

An interesting innovation has been tried with great success at the National Library of Paris. It has been suggested by M. Belliard, one of the principal librarians, who was appointed the head of the Receiving Office a few months ago, to publish a monthly paper containing a descriptive list of the works which have been presented to the library, or purchased during the preceding months. The works sent by the Home Office for the *dépôt legal* are not registered in that paper: there is for these a special publication. The first number has been issued, and is a lithographed 12mo pamphlet of thirty-two pages, having about two hundred entries. A copy will be presented to the great libraries abroad and in France.

Mr. A. J. Harvey, known to many as the advocate of various schemes of social improvement, now propounds a scheme for a "People's Museum of Physical Astronomy, to be erected and endowed by Government." "The object and design of a Museum of Physical Astronomy," Mr. Harvey states, "should be to popularise, familiarise, enlighten, and instruct the people in whatever can be illustrated, taught, and told, through the eye alone and without the aid or necessity of books, &c., of Physical Astronomy." It should be "a museum worthy of the intelligence and wealth of this great country, in which the whole visible universe is roughly presented to us, exhibited upon a colossal yet exact scale, and wherein the actual motions of the heavenly bodies are visible to the naked eye, wherein vast space can be spanned by the hand and great epochs of time counted with ease by the mind."

We have received from Messrs. Blackwood and Sons an interesting lecture by Dr. Page, entitled "Recreative Science; a Plea for Field Clubs and Science Associations." It ought to be circulated extensively among our field-clubs and other local scientific societies.

One of the most important of the many valuable U.S. Government documents published during a few months past is the Annual Report of the United States Geological and Geographical Snrvey of the Territories for 1873, as prepared by Dr. Hayden, being a volume of 730 pages, profusely illustrated with plates and sections, and exhibiting the physical geography, the sectional geology, the mining, and the natural history of the country. The volume consists of several sections. The first, that of Geology, Mineralogy, and Mining Industry, was prepared by Dr. Hayden, Mr. Marvine, Mr. Peale, and Dr. Endlich. The second embraces special reports on Palæontology, on the Fossil Flora, by Prof. Lesquereux, and on the Vertebrates by Mr. Cope. Part third, Zoology, contains articles on the recent Invertebrates, by Lieut. Carpenter, Dr. Packard, Baron Ostensacken, Mr. Ulke, Dr. Hagen, Mr. S. J. Smith, Prof. Verrill, and Mr. William G. Binney. Part fourth, upon the Geography and Topography, is from the pen of Mr. James T. Gardner, geographer of the expedition. There is also an appendix by Mr. A. R. Marvine.

The Rev. G. H. Hopkins gives the following method for fixing the curves which steel filings take when under the action of a bar magnet. The filings having been prepared so as to be as nearly the same size as possible, and that size very minute, are pound into a mortar, and a small quantity of finely powdered resin is added; these are stirred together until the two substances are completely mixed, and then, considerable pressure being exerted upon the pestle, they are rubbed until the resin adheres to the filings in a very fine coating. The filings can then be sprinkled as usual, and the curves formed. It is best (after the curves are formed) to heat the plane surface, glass, paper, or wood, according to convenience, over a stove or in an oven, which easily allow it to be sufficiently as well as uniformly heated. For projecting the curves on a screen, the following, we believe, is a very effective method. Cover the glass with thin gum-water, allow it to dry perfectly; obtain the curves on the dry gummed surface; finally, breathe on the plate: the gum is thereby softened and the curve permanently fixed. Substituting corresponding shaped pieces of paper for the magnets (a pinhole can be used to indicate the N. pole), the curves can be covered with a second plate of glass, and thus preserved as an ordinary lantern slide.

A very satisfactory report has been issued for the past year by the committee of the Devon and Exeter Albert Memorial Museum, &c. Several valuable additions in natural history have been made to the Museum, and in the reference library there has been an addition of eighteen per cent. in the issue of works on science and art. The institution as a whole continues to work so well that more room and better accommodation are urgently demanded.

The additions to the Zoological Society's Gardens during the past week include a Grey-cheeked Monkey (*Cercocebus albigena*), a Marsh Ichneumon (*Herpestes paludosus*), an Angolan Vulture (*Gypohierax angolensis*) from W. Africa, presented by the late Mr. H. Ansell; a Syrian Bear (*Ursus syriacus* from Western Asia, presented by Mr. W. Kirby Green; an Australian Cassowary (*Casuarius australis*) from Australia, presented by Mr. E. P. Ramsay; a Black-necked Stork (*Xenorhynchus australis*) from Australia, presented by Mr. C. Moore; two Egyptian Geese (*Chenalopex ægyptiaca*) from W. Africa, presented by Mr. R. B. N. Walker; three Chestnut-eared Finches (*Amadina castanotis*) from Australia, presented by Mrs. G. French Angas; a Common Raccoon (*Procyon lotor*) from N. America, presented by Mr. Wesson; a Reeves's Muntjac (*Cervulus reevesi*) born in the Gardens.

SCIENTIFIC SERIALS

The American Journal of Science and Arts, May.—The first article is a continuation (No. 5) of a series of notices on recent earthquakes, by Prof. Rockwood. The second is an inquiry by Prof. J. D. Dana on Dr. Koch's evidence with regard to the contemporaneity of Man and the Mastadon in Missouri. (See Note, p. 96.)—Mr. Carey Lea communicates a short note on the influence of colour upon reduction of light, and Prof. Rowland a description of a new diamagnetic attachment to the lantern.—The geological articles are the Primordial Strata of Virginia, by W. Fontaine, and the Age of the Southern Appalachians, by F. H. Bradley.—The contributions from the Physical Laboratory of Harvard College are on the construction of Gaugain's galvanometer, on a new form of magneto-electric engine, by W. R. Morse, and some remarks by S. Newcomb on the Transit of Venus.

The *Journal de Physique théorique et appliquée*, April 1875, contains the following original papers:—Researches on thermodiffusion, by J. Violle.—Determination of the velocity of light and of the sun's parallax, by M. A. Cornu.—On some polarisation experiments, by M. Bertin (last paper).—On an apparatus destined to get glass penetrated by the electric spark, by MM. Terquem and Trannin.—The number contains also several abstracts from papers taken from other serials.

Der Naturforscher, March 1875.—From this part we note the following papers:—On the influence of the density of metals upon their magnetisation; new researches made by Herr Börnstein with iron, nickel, and cobalt.—On the meteorite of Roda (in the Spanish province of Huesca), by Herren Tschermak and Lang.—On the genetic classification of the flora of Australia, by C. von Ettinghausen.—On the shooting stars observed on Nov. 13 and Dec. 10, 1874, at the Toulouse Observatory, under the direction of M. Gruey.—On vegetable mucus, by Herren Kirchner and Tollens.—On the action of hydrochloric acid upon lead-antimony alloys, by Herr H. v. d. Planitz.—On the behaviour of hydrocarbons under restricted oxidation, by M. Berthelot.—On

the star system 61 Cygni; discussion of M. Flammarion's latest papers on the subject.—On the repulsive power of comets, by G. V. Schiaparelli.—On the respiration of Fungi, by Herr Müntz.—On over-saturated solutions and the dissociation of salts in solution, by A. Tscherbatschew.—On forests, the courses of rivers, and atmospheric moisture, by L. Fautrat.—On the radiation of the sun; observations made at the Observatory of Montsouris, near Paris, by Marié-Davy.—On the time of reaction of the sense of taste at the tip of the tongue, by Herren M. v. Vintschgrau and J. Hönigschmied.—On colouring matters and the sensitiveness towards light of several silver salts, by H. W. Vogel.—On the decomposition of vegetable xanthophyll by light, by J. Wiesner.—On the circulation of ammonia in the atmosphere, by Herr Al. Schloesing.—On some glacier-phenomena in the Bavarian high plateaus; a communication made to the Munich Academy, by Herr Zittel.—Researches on the process of digestion in the intestines of sheep, by Eugen Wildt.—Some researches on magnetism, by M. Bouty.—On the antiseptic properties of salicylic acid; an extract from the *Journal für praktische Chemie*, by Herr Kolbe.—On the direct observation of the atmosphere of Venus, by C. S. Lyman; results of these observations show the horizontal refraction of Venus' atmosphere to be $44'\cdot5$; in 1866 it had been determined at $45'\cdot3$, and Mädler in 1849 had found it $43'\cdot7$. Mr. Lyman measured the diameter of the planet six times on Dec. 10 (the day after the transit), and found it on the average to be $63''\cdot1$; the average of eleven measurements on Dec. 11 was $63''\cdot75$.—On the electric action of a thermal source at Baden, Switzerland, by Herren Thury and Alb. Minich.

Zeitschrift der Oesterreichischen Gesellschaft für Meteorologie, March 15.—On the relation between differences of atmospheric pressure and velocity of wind, according to the theories of Ferrel and Colding, by Dr. Hann. The author begins with a review of the two theories of storms, the older of which has been accepted chiefly in Germany, the other in America and the Northern States of Europe. According to the former, whirlwinds are formed mechanically by different streams of air meeting, and centrifugal force causes the central depression. The more modern theory regards a local depression as the first condition, causing an indraught resulting in a whirlwind through the earth's rotation. The primary depression is held to follow condensation of vapour. Probably there is something right in each of these views. Eddies can, doubtless, be formed by currents meeting at certain angles, but the direction of rotation would not be invariable in each hemisphere. Besides, the mechanical resistance to the progress and continuance of a whirlwind so formed would, without inconceivably favourable conditions, be far too great to be overcome. Dr. Hann recognises the part played by vapour in storms, but thinks that many meteorologists rely too much on it in their need, and points to the works of Hopkins and Laughton for instances of this partiality. He believes that the greater part of the low pressure which accompanies storms must be explained by mechanical laws, and that the local differences of pressure in a cyclone or even in a straight-blowing current (if such there be) follow from movements of the air. Condensation may cause a depression, and that depression we know may cause winds which produce a depression ten or fifteen times greater. Prof. Ferrel endeavours to show mathematically that depressions are due to centrifugal force and the earth's rotation. Colding considers tropical hurricanes as true whirlwinds, and his values for pressure from centre to edge reckoned from this hypothesis agree with observation. Now, there is no reason why centrifugal force should not act in spirally-whirling storms in relation to radius and velocity. The earth's rotation adds to the effect of this force, and the result is a diminution of pressure towards the centre on the earth's surface. The enormous extent of some minima is thus explained, which an ascending current and precipitation fail to account for. Dr. Hann proceeds to develop mathematically the theories of Ferrel and Colding, and gives the following formula (1) for finding the barometric gradient:—

$$\Delta B = \frac{l}{287\cdot4} \cdot \frac{B}{T}(2n \sin.\phi + u)v$$

where B is the height of the barometer at point of observation, T the absolute temperature (*i.e.* $273^\circ + t$), $l = 50$ geographical miles, u the angular velocity of rotation, n the angular velocity of the earth's rotation, ϕ the latitude, and v the distance traversed in unit of time. In this equation it is assumed that the circulation is simple, without friction, and not inducing new masses of air.—In the *Kleinere Mittheilungen* we have an article on Baumhauer's Meteorograph, and some extracts from a letter of Prof. Mohn, dated 21st December last, on cyclonic minima. In this letter the writer states that having called the attention of Herr Guldberg to the fact that Colding's point of view is quite different from that of the new school of meteorologists, that gentleman worked out his own formula and found as much agreement between his results and observations of an Antilles hurricane as Colding found by his method. The factors taken into consideration by Herr Guldberg were, barometric gradient, rotation of the earth, centrifugal force, and friction of the air. Prof. Mohn believes the central minimum to be a mechanical effect of rotation. He discovered lately that Prof. Ferrel had worked with similar formulæ and had derived therefrom similar results, but he intends to pursue his task, and believes it will be ascertained that relations of pressure are in great part functions of movement.

THE *Bulletin Mensuel de la Société d'Acclimatation de Paris* for February gives the customary yearly summary by M. Quihou of the principal experiments carried out in the Jardin d'Acclimatation in the Bois de Boulogne during 1874, and of the most important plants cultivated there. — M. Jeannel gives a report on various experiments conducted by him during the year in the Jardin de Luxembourg with the object of testing the value of mineral manures in horticulture.—The new kind of silkworm, *Attacus Yama-mai*, is the subject of a long paper by M. F. A. Bigot.—An attempt made by M. Victor Fleury to acclimatise the Siberian rabbit in France has not entirely succeeded, but excellent results have ensued in the crossing of this race with the common grey rabbit of the country.—The value of the *Eucalyptus globulus* in correcting the unhealthiness of marshy and other lands is proved by its effect in certain parts of Algeria, where, in the neighbourhood of Lake Fezzara, in Constantine, a large area of land hitherto noted for its insalubrity has greatly improved since the plantation of a large number of these trees.

Annali di Chimica applicata alla Medicina, Feb. and March, 1875.—These numbers contain the following papers:—On diastase and some preparations from malt, by H. Duquesnel.—On croton-chloral, by Engel.—On a carbonic solution of tribasic phosphate of lime, by Chevrier.—On a glycerine solution of iodide of potassium, by C. O. Barberis.—On the ventilation of closed localities, by G. P.—On vinic alcohol, aldehyde, and ethers: experimental researches made in the Physiological Laboratory of Padua, by Drs. P. Albertoni and F. Lussana.—On ferments and fermentations in the human organism, by A. Pavia.—On some fermentation processes by J. Macagno.—On a simple, easy, quick, and certain means to distinguish in mankind real death from apparent, by Dr. A. Monteverdi. This consists of injecting under the skin an aqueous solution of ammonia, and watching the appearance of the blister produced.—On blood fibrine and the formation of a substance analogous to ordinary albumen, by A. Gautier.—Researches on the parasite that produces whooping-cough, by Dr. Lebrerich.—On apomorphia, by G. Hirne.—A note on cremation, by the editor of the *Annals*, Dr. G. Polli.

THE *Gazzetta Chimica Italiana*, fasc. iii. 1875, contains the following papers:—On the action of acetyl chloride upon santonine and santonic acid, by F. Sestini.—On some derivatives from alphatoluic acid, by C. Colombo and P. Spica.—On the formation of sugar in fruits, by M. Mercadante.—On a new method of determining the tannic acid contained in wines, by A. Carpané.

SOCIETIES AND ACADEMIES

LONDON

Linnean Society, May 6.—Anniversary Meeting.—Dr. G. J. Allman, F.R.S., president, in the chair.—The officers of the Society were elected for the ensuing year as follows, viz.:—President, Dr. G. J. Allman, F.R.S.; Treasurer, Dr. J. Gwyn Jeffreys, F.R.S.; Secretaries: T. Currey, F.R.S., and St. George Mivart, F.R.S.; and as Members of the Council: Dr. J. D. Hooker, Pres. R.S.; Dr. J. G. Jeffreys, F.R.S.; Major-General Scott, C.B.; R. B. Sharpe, and Chas. Stewart, in the place of J. Miers, F.R.S., T. P. Pascoe, Major-General Strachey, F.R.S., Dr. H. Trimen, and the late D. Hanbury, F.R.S. The President then delivered an address on the History and Development of the Infusoria.

Anthropological Institute, May 25.—Col. A. Lane Fox, president, in the chair.—Mr. T. G. B. Lloyd read papers on

the Beothucs of Newfoundland, and on the Stone Implements of Newfoundland. The first paper was a continuation of one read the previous session, and contained the further experiences of the author in Newfoundland, which island he had recently revisited. The Beothucs possessed several of the characteristics belonging to many of the tribes inhabiting North America, whilst they differed from them in the following peculiarities:—Lightness of complexion, the use of trenches in their wigwams for sleeping places, the peculiar form of canoe, the custom of living in a state of isolation apart from the white inhabitants of the island, and their persistent refusal to submit to any attempts made to civilise them. They were also remarkable for their inability to domesticate the dog.—Prof. Busk communicated a paper on two Beothuc skulls, and described them as presenting all the characteristics of the normal brachycephalic form of the Red Indian skull.—In his second paper Mr. Lloyd described the stone implements he had brought from Newfoundland, consisting of axes, chisels, gouges, spear and arrow heads, scrapers, fish-hooks; also cores, flakes, whetstones, rubbing stones, sinkers, and stone vessels.—Mr. Park Harrison exhibited and described five photographs, from Tahiti, of Easter Island wooden tablets; and Mr. H. Taylor exhibited a series of fine photographs of people inhabiting the South Sea Islands.

Royal Horticultural Society, May 12.—Scientific Committee. A. Murray, F.L.S., in the chair.—The Chairman made a communication with respect to the acarus to which Prof. Thiselton Dyer had drawn attention as destroying the female flowers of the Yew. He believed it to be undescribed, and proposed for it the name of *Tetranychus taxi*. It was allied to the acarus which Prof. Westwood had described as very injurious to the young buds of the currant.—Mr. M'Lachlan exhibited specimens of wallflower in which the petals were virescent.—Dr. Masters showed leaves of the vine (from a nursery in the neighbourhood of London) bearing galls produced by Phylloxera.—Prof. Thiselton Dyer called attention to a paper by Dr. Franz Low, translated in the current number of the *Annals and Magazine of Natural History*. It described a nematoid worm (*Tylenchus Millefolii*), which produced the galls on the rachis of the leaves of the common Milfoil.—Prof. Thiselton Dyer exhibited three flasks which contained Pasteur's solution, all three of which had been subjected to boiling. The neck of No. 1 flask, treated on March 3, 1875, was plugged, while the contents were still boiling, with cotton-wool, and the fluid remains clear and unaffected. In flask No. 2, otherwise similarly treated, but without any plug, so that access of air and therefore of spores was allowed, there was a dense growth of mould (*Penicillium*). In No. 3, boiled on Sept. 30, 1873, but in which the plug was removed for five seconds only on Oct. 15, 1874, a dense mould had made its appearance.

General Meeting.—W. Burnley Hume in the chair.—Prof. Thiselton Dyer called attention to the principal objects exhibited.—A fine potful of the rare Irish Butterwort, *Pinguicula grandiflora*, was shown by Mr. Dean. *Senecio macroglossus*, an evergreen greenhouse climber shown by Mr. Green, had foliage identical with that of some forms of ivy; it was a native of the Cape.—A ripe fruit of *Stephanotis floribunda* was sent by R. T. Coombe, Taunton. Morels, which are abundant this year, were represented by a fine series of *Morchella crassipes*, sent by J. Barclay, The Durdans, Epsom.

Physical Society, May 22.—Prof. Gladstone, F.R.S., president, in the chair.—Mr. Spottiswoode, F.R.S., exhibited and described a revolving polariscope. A luminous beam passes from a small circular hole in a diaphragm through a polariscope, the analyser of which is a double image prism, the size of the hole being so arranged that the two luminous discs shall be clear of each other. If the prism be made to revolve rapidly, one of the discs revolves round the other and is merged into a ring of light, which is interrupted at opposite sides by a dark shaded band, the position of which depends upon the position of the original plane of polarisation. The discs may be coloured by inserting a selenite plate, and the rapid revolution of the analyser then gives alternating segments of complementary colours; or, if a quartz plate be used, the rotating disc passes successively twice in a revolution through all the colours of the spectrum, and when the revolution is rapid, merges into a prismatic ring. The effect of the interposition of a $\frac{1}{4}$-undulation plate, which converts plane into circularly polarised light, was then shown, and Mr. Spottiswoode also interposed a concave plate of quartz, and exhibited the effect of rotation on the characteristic rings of quartz.—Prof. Adams exhibited a polariscope adapted for showing the optic axes of crystals in which they are much inclined to each other, as in the case of topaz. The part of the instrument by which this is effected consists of a frame in which the crystal is supported between two hemispherical lenses, the common centre of which is at the centre of the crystal. The frame is capable of motion round an axis at right angles to that of the instrument. By this means each of the axes can be brought under the cross wires, and the space through which the frame is moved affords a means of determining the angle between the axes of the crystal. The crystal may be immersed in a liquid in cases in which its optic axes are too far apart to be seen in air.—Dr. Mills made a verbal communication on fusion-point and thermometry. His apparatus for fusion-points consisted essentially of a beaker, in which stood an inverted funnel, the shortened stem of which carried a test-tube, supported by a contraction at its base. The test-tube contains naphtha of high boiling-point, and the thermometer and capillary tube containing the substance occupy its centre; the funnel has four equidistant semicircular cuts at the end of its stem, and six on its lips; the beaker is nearly filled with strong oil of vitriol, and has a wooden cover; on the application of heat below the beaker, warm oil of vitriol ascends in the funnel, and cold oil of vitriol descending, enters at the lip; thus an automatic stirring is kept up, and the mercury in the thermometer rises so regularly as to appear perfectly continuous in course, even under considerable magnifying power. The manner of preparing and filling the capillary tubes was described. Attention was then drawn to the "zero error" of thermometers. In thermometers which have not been much used, the zero error must always be determined immediately after experiment. It is also generally necessary to correct for the projection of the thermometer beyond its bath. This correction has been experimentally determined by the author, and required from 1,500 to 2,000 observations of temperature for each of four instruments used. It was ascertained that the well-known expression—

$$C = \cdot0001545\ (T - t)N$$

given by Regnault and Kopp is not supported by actual trial. If we write the expression thus—

$$C = x(T - t)N$$

experiment shows that x depends on the length N exposed, and

$$x = \alpha + \beta N$$

For lengths of about 25°, x is about ·00013, and increases about ·0001 for every additional 25°. The exact values of α and β require, however, to be ascertained for each instrument.—Mr. Bauerman, F.G.S., described and illustrated a very simple method for ascertaining the electric conductivity of various forms of carbon. The method, which was originally devised by Dr. von Kobell, consists in holding a fragment of the substance to be tested with a strip of zinc bent in a U-form, and immersing it in a solution of copper sulphate. In the case of a bad conductor a deposit of copper takes place solely on the surface of the zinc, but when a good conductor is employed a zinc-carbon couple is formed, and a deposit takes place on the surface of the carbon. Numerous specimens were exhibited which showed that the conducting power is greatest in coal which has been subjected to a great degree of heat, and the lowest temperature at which this change takes place appears, in the case of anthracite, to be between the melting points of zinc and silver. Such experiments appear to be specially important as giving a clue to the temperature at which anthracitic metamorphism has been effected by the intrusion of igneous rock.—Prof. Woodward exhibited an apparatus for building up model cones and craters. It consists of a wooden trough about 18 inches long, with sloping sides; at the bottom of the trough a bladed screw carries forward the ashes, sawdust, or other material used, to an opening through which air from a powerful bellows is forced upwards. A board 3 or 4 feet square, with a hole in the centre, is placed over the air-jet, and on this the crater is formed. Several of the peculiarities of natural cones may thus be illustrated, and their structures shown, by using sawdust of various colours.

WELLINGTON, N.Z.

Philosophical Society, Feb. 10.—Dr. Hector, F.R.S., in the chair.—The annual report by the Council (adopted as read) congratulated the Society upon its prosperous condition, not only in regard to the great increase in the number of members, but upon the growing interest taken in the work of the Society, as indicated by the large attendance at the meetings of the past session, and by the number of interesting papers read and dis-

cussed by members. There are now 161 names on the books, twenty-two new members having been elected since January 1874. Seven general meetings were held, and thirty-two papers read on the following subjects :—*Geology*.—1. Did the Great Cook River run N.W. or S.E.? Mr. Crawford. 2. On the Tertiary Series of Wanganui, Mr. Purnell. 3. On the microscopic structure of the igneous rocks of New Zealand, Richard Daintree. 4. On the Pleistocene glaciation of New Zealand, Mr. Travers. 5. Changes in the physical geography of New Zealand since the arrival of the Maoris, Mr. Hood. *Zoology*.—1. Description of fish, presented to the Museum by Prof. Wyville Thomson, Dr. Hector. 2. On new fish from Chatham Islands, Dr. Hector. 3. On certain disputed points in New Zealand Ornithology, Dr. Buller. 4. On New Zealand whales, Dr. Hector. 5. On *Plotus novæ hollandiæ*, Dr. Buller. *Botany*.—1. On a new species of *Rubus*, by Mr. Buchanan. 2. On the durability of New Zealand timber, Mr. Buchanan. 3. On *Juncus camprocarpus* and a new species of Isoetes, Mr. Kirk. 4. On new species of mosses, Dr. Knight. 5. Flowering plants and ferns of Chatham Islands, Mr. Buchanan. 6. Description of New Zealand lichens, Dr. Knight. 7. Two plants new to New Zealand, *Lepilæna preissii* and *Carex chlorantha*, Mr. Kirk. *Meteorology*.—1. On solar radiation in New Zealand, Mr. Rous Marten. 2. On the hot winds of Australia and their influence on the climate of New Zealand, Mr. Hood. 3. On the hot winds of Canterbury, Mr. M'Kay. *Chemistry*.—Five papers pointing out certain new discoveries in chemistry, Mr. Skey. *Miscellaneous*.—1. On ergot in rye, Dr. Hector. 2. On portion of a wreck found at the Haast River, Capt. Turnbull. 3. On the identity of the Moa hunters with the present Maori race, Mr. M'Kay. 4. On Maori traditions respecting the Moa, Mr. Hamilton. 5. On the longitude of Wellington Observatory, Capt. Nares, of H.M.S. *Challenger*. 6. On the Duplex system of telegraphy, Mr. Lemon. These papers will all appear in the seventh volume of the "Proceedings and Transactions of the New Zealand Institute," which is now going through the press. The balance-sheet showed a credit of 162*l*., of which Dr. Hector was requested to expend 100*l*. in purchasing standard works of reference in England.—The Chairman announced that Prof. Wyville Thomson, Prof. Newton of Cambridge, and Robert M'Lachlan, all of whom had taken great interest in New Zealand science and added much to its literature, had been elected honorary members of the New Zealand Institute. Dr. Buller, F.C.S., F.G.S., was elected president for the ensuing two years. Mr. Travers, F.L.S., vice-president, then took the chair, and the following papers were read :—Further proofs of the former existence of the Great Cook River, by J. C. Crawford, F.G.S.—Notes on Hutton's "Catalogue of Marine Mollusca of New Zealand," by Dr. Ed. von Martens.—On some additions to the collection of birds in the Colonial Museum, by Dr. Buller.—Additional notes on New Zealand fishes, by Dr. Hector.—Further notes on New Zealand whales, by Dr. Hector.—Mr. Travers said that the visit of Dr. Hector to Europe with a valuable collection of specimens of natural history and other objects would materially advance the cause of science in New Zealand.

PHILADELPHIA

Academy of Natural Sciences, Sept. 15, 1874.—Dr. Ruschenberger, president, in the chair.—Prof. Leidy made some remarks on the moving power of diatomes, desmids, and other Algæ. While the cause of motion remains unknown, some of the uses are obvious. The power is considerable, and enables these minute organisms, when mingled with mud, readily to extricate themselves and rise to the surface, where they may receive the influence of light and air. In examining the surface-mud of a shallow rainwater pool, in a recent excavation in brick clay, he found little else but an abundance of minute diatomes. He was not sufficiently familar with the diatomes to name the species, but it resembled *Navicula radiosa*. The little diatomes were very active, gliding hither and thither, and knocking the quartz sand-grains about. Noticing the latter, he made some comparative measurements, and found that the Naviculæ would move grains of sand as much as twenty-five times their own superficial area, and probably fifty times their own bulk and weight, or perhaps more.—Dr. J. Gibbons Hunt remarked that in the vegetable kingdom it is exceedingly rare to meet with glands which have distinct excretory ducts. Some authors deny their existence entirely; but in *Nepenthes rafflesiana*, *N. distillatoria*, and *N. phyllamphora*, and probably in all the species, are large cylindrical glands which pour out their secretion through distinct excretory ducts.

PARIS

Academy of Sciences, May 20.—M. Frémy in the chair.—The following papers were read :—Observations of the moon, made with the meridian instruments of the Paris Observatory during 1874, communicated by M. Leverrier.—Some remarks on the discussion with regard to cyclones, by M. Faye.—Researches on sun-spots and solar protuberances made during the years 1871 to 1875, by Father Secchi.—Conditions of the maximum amount of work produced by heat-engines, by M. A. Ledieu.—M. André read a paper on the scientific results obtained at Nouméa by the Transit party.—On the determination of singularities of the left curve, at the intersection of two surfaces of any order that have a certain number of multiple points in common, by M. L. Saltel.—A note by M. V. Cornil, on the dissociation of the violet of methylaniline and its separation into two colours under the influence of normal and pathological tissues, particularly by tissues inclined to amyloid degeneration.—Application of the graphical method to the study of the mechanism of swallowing, by M. S. Arloing.—On a new proceeding in the operation of the cataract (extraction by means of a peripherical piece of cloth), by M. L. de Wecker.—Sulphuration of copper and of iron by a prolonged presence in the thermal source of Bourbon-l'Archambault, by M. de Gouvenain.—On the wanderings of the oak Phylloxera, by M. Lichtenstein.—On some reactions of chromium salts, by M. A. Etard.—On Camphenes, by M. J. Riban.—A note by MM. C Saint-Pierre and G. Jeannel, on a reaction of carbon bisulphide; conversion of carbon bisulphide into hydro-sulphocyanic acid.—On the influence of the pressure in the atmosphere upon the life of man, by M. Cl. Bernard.—Researches on the respiration of birds, by the same and M. Campana.

BOOKS AND PAMPHLETS RECEIVED

BRITISH.—The Pebbles in a Bolton Brick-field. A Lecture by Rooke Pennington, B.A., LL D. (*Bolton Daily Chronicle*).—Report of the Rugby School Natural History Society for 1874.—Notes on the Fertilisation of Cereals (Botanical Society of Edinburgh).—On the Graphical representation of the movements of the Chest Wall in Respiration: A. Ransome, M.D., M.A. (Taylor and Francis).—Arctic Papers for the Expedition. A selection of Papers on Arctic Geography and Ethnology. Printed and presented to the Arctic Expedition of 1875 by the Royal Geographical Society (John Murray).—A Compendious Statement of the Nature and Cost of certain Sewage Processes: Major-General Scott, C.B.—Ornithology of the Straits of Gibraltar: Lieut.-Col. L. Howard and L. Irby, F.Z.S. (R. H. Porter).—Contributions to Natural History and Papers on other Subjects: James Simpson (Edinburgh Publishing Company).—Recreative Science: David Page, LL.D. (Wm Blackwood).—Transactions of the Norfolk and Norwich Naturalists' Society, 1874–75. Vol. ii. Part i.—The Potato Disease: Eccles Haigh (G. Philip and Son).—Chapters on Sound: C. A. Martineau (Sunday School Association) —The Zoological Record for 1873 (John Van Voorst).

COLONIAL.—General Report on the Operations of the Great Trigonometrical Survey of India during 1873–74: Col. J. T. Walker, R.E., F.R S., &c., Superintendent of the Survey (Dehra Dun, M. J. O'Connor).—Proceedings of the Annual Meeting of the Members of the Agri-Horticultural Society of Madras on the 24th and 27th of March, 1875.

AMERICAN.—Centrifugal Force and Gravitation. Part I.: John Harris (Lovell Printing and Publishing Company).—The Surface Geology of Ohio, U.S. (Columbus, O.; Nevins and Myers).

CONTENTS

THURSDAY, JUNE 10, 1875

THE METEOROLOGICAL OFFICE

Quarterly Weather Report of the Meteorological Office. Published by the authority of the Meteorological Committee, January 1869, to September 1873. Hourly Readings from the self-recording instruments at the seven Observatories in connection with the Meteorological Office, January to September 1874.

THE self-recording instruments which have been in operation at the seven Observatories of the Meteorological Committee since January 1869, may be regarded as the best and most complete anywhere existing for recording continuously the atmospheric pressure, temperature, humidity and rainfall, and the velocity and direction of the wind. To ensure correctness in the work, and accurate tabulation of the results, minute regulations with respect to the officials at the outlying Observatories, the assistant at the Central Observatory, and the director of the Central Observatory, were laid down in the Committee's Report for 1868, p. 62. Thus, as regards the thermograph, twenty-seven regulations were laid down, one of the most important of these being the 25th, by which it was provided that forty remeasurements from each month's curves were to be made at Kew, the central Observatory; and a table is given (page 39 of the same Report) of the results of measurements which were specially designed for the detection of *small errors* in the thermograph tabulations, from which it appears that refinements as minute as the one-hundredth of a degree of temperature were taken cognisance of in the results.

Tracings of the curves, and five-day and monthly results of the tabulations, though not the tabulations themselves, have been published, beginning with 1st January, 1869; and since then many and great improvements have been made in representing the curves on the Plates, all in the direction of greater clearness and precision, for which the Committee deserve our best thanks. Among the many valuable results of these curves we may point to the high temperature at Glasgow on the 21st April, 1873, in connection with the remarkable changes in the direction and force of the wind which occurred at the time; to the heavy rainfall at Valencia on the 2nd July, 1873, in connection with the changes of wind, temperature and pressure; and to the minute oscillations of pressure at almost all the Observatories on the 3rd and 4th July, 1873, in connection with the changeable weather at the time. In these connections the absence of any observations of clouds is, however, a serious defect.

One of the principal objects for which the seven Observatories were established was to furnish the data of observation for the determination of the meteorological "constants" for pressure, temperature, rainfall, &c., for different parts of the British Isles. This being now the seventh year in which this expensive system of observation is going forward, it may be well to inquire how far the information, as published by the Meteorological Office, meets the requirements of the problems to be solved.

Assuming that the curves are correctly traced from the photographs, we may inquire whether the figures tabulated from these, under the regulations referred to above, be satisfactorily accurate. No hourly values having been printed before January 1874, the question can only be answered by an examination of the printed monthly maxima and minima, with the days and hours of their occurrence, as compared with the curves. The following Table, giving the extreme readings of the thermometer for each of the Observatories for January 1869, is here reprinted verbatim from the Quarterly Weather Report for 1869, Part I., p. 34:—

	Maximum.	Day and Hour.	Minimum.	Day and Hour.
Valencia ...	53°·7	4th, 4 A.M.	37°·0	22nd, 3 A.M.
Armagh ...	53°·1	16th, 2 P.M.	31°·9	26th, 2 A.M.
Glasgow ...	50°·1	5th, 10 A.M.	29°·5	26th, 7 A.M.
Aberdeen ...	48°·8	31st, 6 P.M.	30°·6	26th, 8 A.M.
Falmouth ...	54°·0	30th, noon.	36°·0	24th, 9 A.M.
Stonyhurst...	51°·8	31st, noon.	28°·4	25th, 2 A.M.
Kew	55°·3	30th, 6 P.M.	27°·6	25th, 7 A.M.

Each datum of this table we have compared with the temperature curves for the month, measuring each observation four times, viz., by the side scales of each curve from below upwards, and from above downwards. Setting aside every reading which does not differ from the measured reading so much as 0°·4 of a degree, and the discrepancies which appear to arise from the unequal shrinkage of the paper as indicated by the results of the four measurements, there are in the above Table twelve errors, the maxima at Falmouth and Kew being doubly wrong, the amount at the given hours being wrong, and the date of occurrence being also wrong. The following is the Table as corrected, the corrected readings being shown by asterisks:—

	Maximum.	Day and Hour.	Minimum.	Day and Hour.
Valencia ...	53°·7	* 5th, 4 A.M.	37°·0	22nd, 3 A.M.
Armagh ...	*53°·6	16th, 2 P.M.	*32°·3	26th, 2 A.M.
Glasgow ...	*50°·9	5th, 10 A.M.	*27°·0	* 1st, 2 A.M.
Aberdeen ...	48°·8	31st, 6 P.M.	*28°·7	* 1st, 4 A.M.
Falmouth ...	*54°·9	*31st, 11 P.M.	36°·0	24th, 9 A.M.
Stonyhurst...	51°·8	31st, noon.	*22°·8	* 1st, 8 A.M.
Kew	*55°·8	*31st, 1 P.M.	27°·6	25th, *5 A.M.

It will be observed that the errors are of three sorts—(1) errors of temperature and errors of the date of occurrence of the maxima and minima, including (2) errors of the day of the month, and (3) errors of the hour of the day. Similarly the other months of 1869 have been examined, with the result that forty-one errors of temperature varying from 0°·4 to 9°·6 † have been detected, that the day of the month, as printed, is wrong on twenty-two occasions, and that the hour of the day is wrong in nine cases, in which the temperature and day of the month are correct—in all, seventy-two errors. The Tables and curves for ten months, taken indiscriminately from the other years, have also been examined.

In the Tables for April and June 1870 (p. 37 of the Quarterly Weather Report of that year) there occur six errors in each of these months, and in the Table for March 1871 (p. 26 of Q. W. Report for 1871) there occur seven errors. In none of the twenty-two months examined are there

† The minimum temperature at Glasgow for October is given as 39°·9 at p. 109 of Q. W. Report, instead of 30°·3 as by the curve of temperature (Plate cxix.).

fewer than two errors. This is the number of errors in the Table for August 1873 (p. 42 of Q. W. Report for 1873), being the last month for which the whole of the curves have been published. One of these two errors has reference to the minimum temperature for Aberdeen (39°·2) which occurred at 4 A.M. of the 11th August, and regarding which the following remark is made in a footnote :—"Doubtful; instrument out of action immediately after 6 A.M." If we turn to the Aberdeen temperature curve of the 11th (Plate xlv.), we see that the instrument was not out of order during the whole of that day; and by examining the curve for the whole month, we see further that the instrument went out of action on no day at 6 A.M., and that on the six occasions on which it was out of order during the month, it is highly probable that in none of the cases did the temperature fall so low as 39°·2.

Tables of errata for 1869 have been published by the Office from time to time, the last one appearing in November 1874. Not one of the numerous errata referring to 1869, as well as those referring to the other years, which have been detected in this examination, has yet appeared in the Tables of errata published by the Office. Furthermore, these Tables of errata are themselves repeatedly in error; thus, the last one, printed on the title-leaf of the Quarterly Weather Report for July—Sept. 1873 contains in the five lines which compose it no fewer than three mistakes; viz., 1874 being twice printed for 1873, and the hour of occurrence of the minimum at Glasgow being curiously printed as 0^h 2 A.M., whereas the month began with the minimum temperature.

As the curves for 1874 are not yet published, there are no means of checking the hourly tabulated readings from the curves. Referring, however, to the regulations laid down for the detection and correction of *small errors*, and to the minute refinement to which the results were to be carried, viz., to the hundredth of a degree, we were led to expect that the tabulated readings would be taken from the curves with an approach to accuracy of at least the tenth of a degree. A slight inspection of the figures of the tabulated readings shows at once that this is not the case, with the single exception of the Observatory at Stonyhurst.

A word will explain our meaning. There being no reason why any one of the ten decimal figures, viz., ·1, ·2, ·3, . . . ·8, ·9, ·0 should occur oftener than another, it is evident that on the mean of, say, a month's observations, the number of times on which a reading of a whole degree occurred would be, approximately, a tenth of the whole number of readings. At Kew, however, out of the whole 744 readings for January 1874, 172 whole degrees were read off from the curves and have been printed in the Tables; in other words, nearly 100 in excess of a due proportion. Next month matters improved at Kew, and only 87 whole-degree readings are given; in March they rose to 127, and fell again in April to 94. In this respect Kew shows the greatest irregularity of all the Observatories, but more especially as regards the tabulations from day to day—showing in this respect a marked contrast with the regular business-like tabulations of Stonyhurst. Summing up all the whole-degree readings at each of the Observatories for the nine months, and comparing the results with a tenth part of all the readings tabulated, we obtain the following results :—At Stonyhurst the number of whole-degrees read off were 16 per cent., *less* than a tenth part of the whole; at the other observatories the numbers are *greater* than a tenth part of the whole, in the following order: Kew, 50 per cent.; Aberdeen, 95 per cent.; Armagh, 112 per cent.; Falmouth, 137 per cent.; Valencia, 147 per cent.; and Glasgow, 148 per cent. Every statistician will know the meaning of these figures, and how completely they destroy the scientific character of the work. It should moreover be kept in mind that 1874 was the sixth year of the tabulation by the Observatories of the readings taken from the curves. The method of tabulation as carried out is too rough for the determination even of the temperature daily "constants"—a statement which will be self-evident from the following hourly mean values for Valencia for the month of July 1874, beginning with 1 A.M.: 57°·7, 57°·5, 57°·3, 57°·2, 57°·1, 57°·6, 58°·7, &c.; the curve for the time from 2 to 5 A.M. cannot be determined from observations in which whole degrees so largely preponderate. Though the instrumental arrangements for the continuous registration of the temperature at the Committee's seven Observatories may well be regarded as a triumph of science, yet the results, as tabulated and published, can scarcely lay claim to a higher value than eye-observations of third-rate observers.

In view of the results of this examination, it is not easy to see how one can make a scientific use of the tabulations, and results deduced therefrom, as made by this department of the Office, until (1) the tracings of the curves from the photographs, (2) the tabulations of the hourly values from the curves, and (3) the monthly and five-day means, have been carefully revised.

It cannot be said that the publications have been issued under a press of work in the Office, seeing that the Quarterly Weather Reports have been published just when the Office has been ready to do it. The last published Report is for the quarter ending September 1873, and the last quarter of 1871 only appeared in November last. Further, at page 66 of the Report for 1873, giving a list of persons in the employment of the Meteorological Committee, we learn that at the time of going to press the number so employed was twenty-four, and the sum expended in the year for their salaries amounted to about 3,727*l.*, to which, if we add 2,722*l.* for expenses at Observatories (Report for 1873, p. 32), it is evident that there can be no reasonable doubt that the staff available for this work is amply sufficient.

There is a question yet remaining to be considered, viz., Are the thermometers at these Observatories in positions which will fairly indicate the march of the temperature of each place through the hours of the day; and, above all, are they so placed as to be comparable with each other? In the Introduction to the Quarterly Weather Report for 1870, pp. iii. to vii., woodcut illustrations are given of the thermometer screens, with their positions and surroundings. No two of these are alike—the only approach to uniformity being Stonyhurst and Glasgow. Two of the Observatories, viz., Valencia and Falmouth, occupy important positions near the sea, and might have yielded valuable results with regard to the influence of the sea on climate, but they have been placed in situations so confined that their temperature observations are of little value con-

sidered as contributions to a scientific inquiry into the climate of these islands.

The Council of the Scottish Meteorological Society, in a report dated 3rd July, 1872, drew attention to the positions of the thermometers, particularly those at Aberdeen which are forty-one feet above the ground and surrounded with buildings; giving it as their opinion that "observations so made were not comparable with each other, nor with other observations."* The publication since, by the Committee, of the hourly readings, enables us to examine the point from the observations themselves. One of the best marked phases of the daily temperature, as well as one of the most important, both for scientific and practical purposes, is the increase which takes place from 9 A.M. to 3 P.M. At Kew the mean increase between these two hours for January and February 1874 was 4°·8, and for June and July 6°·7—the greater increase in the summer months being in accordance with the climatic facts. But at Aberdeen the thermometers indicated between the same hours a mean increase of 3°·7 for January and February, and 1°·8 for June and July; thus, instead of being larger in summer, the recorded difference was only half that recorded in winter. It is needless to remark that these results for Aberdeen cannot represent the temperature of this part of her Majesty's dominions, and that for the supplying of data for temperature "constants" for that part of North Britain, the observations made there are worse than useless. The arrangements for the thermometers at the seven Observatories, both as regards height above the ground, and exposure, call for reorganisation.

In Part I. of the Quarterly Weather Report for 1870 (App. pp. 8-10) appears a valuable Table of the mean monthly readings of the barometer at the Committee's telegraphic stations. If we were sure that the method of annual inspection of these stations is a sound one, the results for Holyhead might suggest an inquiry into the influence of the sea on the state of the barometer. The position of the rain-gauges above the ground at these stations, which varies from five inches to 23 feet (Q. W. Report for 1873, Part III., p. 44), calls also for revision.

In all the Reports issued by the Office it will be observed that no monthly mean temperatures for the telegraphic stations have yet been published by the Committee. With reference to these stations, Mr. Symons, in December 1869, remarked: "Various facts brought under our notice convince us that more remains to be done than has yet been effected, and that in many respects these stations [telegraphic] are unworthy of the nation of which they are to a certain extent representative."† We have no means of knowing how far matters have been rectified. It may therefore be doubted, if the Office were asked to furnish meteorological information for the use of the Registrar-General, whether they possess in their own stations the means of supplying it.

We deeply regret the position we have been forced to assume in reviewing the work of the Meteorological Office, but our duty as public journalists leaves us no choice in drawing attention to the work done in return for the annual grant by Parliament of 10,000*l.*

ARCTIC GEOGRAPHY AND ETHNOLOGY

A Selection of Papers on Arctic Geography and Ethnology, reprinted and presented to the Arctic Expedition of 1875, by the President, Council, and Fellows of the Royal Geographical Society. (London: John Murray, 1875.)

WHILE in absolute value the Admiralty Arctic Manual must be regarded as considerably superior to the one before us, still the latter contains a great deal of matter interesting in itself and of high value as adding to our knowledge of the Arctic regions. The Geographical Society deserves thanks for the present it has made to the Arctic Expedition, and we have no doubt that the explorers will find the Selection of real service in enabling them to add to our knowledge in the directions pointed out therein. The editing of the work has been well done by Mr. Clements R. Markham.

The papers in the Geographical Society's "Collection" are arranged under the two main divisions of Geography and Ethnology, although under the former there is much that might be more properly classed under the head of Geology. The first series of papers in the geographical section, occupying about one-half of the space allotted to that section, and about one-fourth of the entire volume, is by Dr. Robert Brown. These papers consist mostly of reprints and condensations of papers by Dr. Brown, which have already appeared in various scientific publications. It seems to us that the value of these papers would have been much enhanced had the author carried condensation much further than he has done. Dr. Brown's style is often painfully slipshod; he frequently indulges in a great waste of words with inadequate result, and it would only have been courteous to those for whose behoof this compilation was made to have revised his papers most thoroughly, stating all the facts as briefly and clearly as possible.

It is unnecessary to enter here in detail into the subjects treated of by Dr. Brown, especially as most of the geological facts have recently been given in NATURE in the series of papers by Mr. De Rance (vol. xi. p. 447, *et seq.*) After describing all that is at present known of the Greenland coast-line, both east and west, Dr. Brown gives a brief account of the few journeys that have been attempted into the interior of Greenland. The country has never hitherto been crossed; if judiciously gone about the feat might very possibly be accomplished. He believes Greenland to be "only a circlet of islands separated from one another by deep fjords or straits, and bound together on the landward side by the great ice-covering which overlies the whole interior, and which is pouring its outflow into the sea in the shape of glaciers and icebergs." The general opinion undoubtedly is, as one of the greatest glacial authorities, Mr. James Geikie, puts it, that "the whole interior of the country would appear to be buried underneath a great depth of snow and ice, which levels up the valleys and sweeps over the hills," though Dr. Brown believes there are no mountains of any extent in the interior. The statement of Dr. Rink, in his paper, reprinted here, "On the Discoveries of Dr. E. K. Kane," seems to us, however, to be more philosophical. "The reality is," Dr. Rink says, "that wherever one attempts to proceed up

the fjords of Greenland, the interior appears covered with ice; but there is no reason whatever to assume that this applies to the central part of the country, in which one, on the contrary, just as well may assume that there are high mountain chains, which protrude partly from the ice." Dr. Rink, moreover, thinks the "ice-fjords point out probably the rivers of the original land, now buried under ice." At present any statements with regard to the interior condition of Greenland must be at best conjectural, though all we know seems to point to its being one sheet of glacial ice, the main flow of the glacier being to the west rather than to the east.

The remainder of the geographical section is occupied by some very valuable papers which the Society have done well to reprint and put in the hands of the members of the Expedition. The paper "On the best means of reaching the Pole," by Admiral Baron von Wrangell, is interesting as being the first proposal to attempt to reach the Pole by the route of Smith's Sound. The paper, moreover, gives some valuable hints as to the method which ought to be adopted in attempting an exploration by this route, and coming as they do from one who has had so great experience in Arctic exploration, they ought to be received with great respect. The paper by Dr. Rink, who may safely be entitled "one of the most eminent living authorities" on many scientific subjects connected with Greenland, on the discoveries of Dr. Kane, we have already alluded to. While admitting the valuable contributions made by Dr. Kane to our knowledge of the geography of the Smith Sound route, Dr. Rink justly criticises the scientific theories broached by Dr. Kane as to the interior of Greenland, the "open Polar Sea," the connection between the Greenland and American coasts, and other points. Dr. Kane's theories are shown to have been based on very insufficient data, and subsequent exploration has only served to prove the justness of Dr. Rink's criticisms.

One of the most careful papers in this section is by Admiral E. Irminger, of the Danish Navy, on "The Arctic Current around Greenland." This paper is based on a thorough examination of the log-books of a large number of Danish ships sailing between Greenland and Denmark. The now generally accepted conclusion he reaches is that the current from the ocean around Spitzbergen, which carries so considerable masses of ice, after it has passed along the east coast of Greenland, turns westward and northward around Cape Farewell, *without detaching any branch* to the south-westward, directly towards the banks of Newfoundland. The current afterwards runs northward along the S.W. coast of Greenland, until about lat. 64° N., and at times even as far up as 67°. Afterwards turning westwards, it unites with the current coming from Baffin's and Hudson's Bays, running to the southward on the western side of Davis Strait, along the coast of Labrador, thus increasing the enormous quantity of ice that is poured into the Atlantic Ocean.

The concluding series of papersin the geographical section is by Admiral Collinson. "The full results of that distinguished officer's remarkable Arctic voyage," to quote the words of the preface, "have never been given to the public; and both the Fellows of the Society and the officers of the Arctic Expedition are to be congratulated on having elicited so valuable an instalment. Admiral Collinson gives his notes on the state of the ice, and on indications of open water, from the mouth of the Siberian river Kolyma, along the shores of Arctic America, to Bellot Strait. He also furnishes a narrative of all the expeditions that have explored the shores of Arctic America, from Point Barrow to the Mackenzie River, and from the Mackenzie to the Back River, including his own voyage, and concludes with some general observations on the ice." The contribution made by Admiral Collinson is really an elaborate one, and must have cost its author much trouble. It affords insight into a variety of points connected with Arctic navigation, but more especially on the tides, the nature of the ice, the set and rate of the currents in Behring Strait, and to the east and west of that along the coasts of America and Asia.

"On the Asiatic side we have indisputable records of open water continuously met with during the period of lowest temperature for a distance of upwards of 1,000 miles. On the opposite shore the ice is driven frequently during the winter by the force of the wind from the coast at Point Barrow, but along the American continent to the eastward the ice, as far as we are capable of judging from one winter's experience, it remains quiet and immovable. Hence comes the question, Does the effect of the Pacific current lose itself in the expanse of the Polar Sea, or does it take an easterly trend? So far as experience guides us, the positions reached by the *Enterprise* in 1850 prove the existence of a loose pack 100 miles to the north-east of Point Barrow; beyond this, until we come to the records given by Sir R. M'Clure, nothing is known, but we have undoubted testimony that the pressure on the north face of Banks Land comes from the westward: and here in this strait, between Melville Island and Banks Land, occurs one of those dead locks in the motion of the ice that are remarkably instructive. . . . . So far as can be gathered from the accounts given, it may, I think, be assumed that the pack is looser, and open spaces of water are more frequent to the north than they are to the south of the Parry Group. . . . Though the Pacific current is in a great measure turned aside from the face of the American continent by the abrupt change in the direction of the coast at Point Barrow, the testimony of all navigators is conclusive that it is felt, and that an easterly set pervades to a greater extent than a westerly one, and that this set is more noticeable to the east of the Mackenzie."

All the papers in the second part of the Selection, that on Ethnology, are valuable. Mr C. R. Markham contributes four papers, the first "On the Origin and Migration of the Greenland Eskimo," being one of the most interesting and instructive in the whole book. Mr. Markham has evidently given the subject careful study, and his hypotheses seem to us to be on the whole sound. For three centuries after the Norse began to settle in Greenland in the end of the tenth century, Mr. Markham believes that no indigenous race was seen in the land; that all at once, about the middle of the fourteenth century, a horde of Skrœllings appeared in the extreme northern frontier settlements of Greenland, and seem rapidly to have stamped out the Norse colonists. Whether this was so or not, there seem to us great probability in the theory of the migration of the Greenland Esquimaux advanced by Mr. Markham. During the centuries preceding the first reported appearance of the Esquimaux in Greenland, the commotions in Central Asia, under Tugrul Beg, Jenghiz Khan, and other leaders, were the means of sending forth swarms of Turks and

Mongols in all directions. The pressure caused by these invading waves on the tribes of Northern Siberia drove them still further to the north. Horde succeeding horde increased the pressure, until at last the Omoki, the Chelaki, the Onkilon, and other aboriginal tribes, were driven quite out of the country, and have long ago disappeared entirely, leaving only traditions of their existence and remains here and there of their *yourts* or dwellings.

Mr. Markham thinks that here we have probably the commencement of the exodus of the Greenland Esquimaux, which spread over a period of one or two centuries. He believes they must have made their way from Cape Chelagskoi to the Parry group, probably over a chain of islands. Still keeping northwards, by Banks Island, Melville Island, Bathurst Island, North Somerset and Devon, Jones' Sound, Carey Islands, on all which undoubted traces of Esquimaux have been found, but where the conditions are not favourable to permanent settlement, the Asiatic emigrants made their way to Smith Sound, which they crossed in parties during the fourteenth, fifteenth, and sixteenth centuries. Some established their hunting grounds between the Humboldt and Melville Bay glaciers, and became the ancestors of that very curious and interesting race of men the Arctic Highlanders. Here the vegetation, the constant open water, and other conditions rendered a permanent settlement possible. Mr. Markham believes that some of these immigrants proceeded southwards and peopled South Greenland; not only so, but that parties also wandered still further north than the Humboldt Glacier, and that it is not improbable that our new Expedition may find groups of Esquimaux up to the very Pole itself. *Nous verrons.* Meantime, we repeat, Mr. Markham's theory seems to us a plausible one, and to answer all the requirements of an immigration into Greenland of a people such as are the Esquimaux. Dr. Rink, however, in a paper on the Descent of the Esquimaux, is inclined to believe them the last wave of an aboriginal American population driven from the interior by the pressure of tribes behind them. This may have been so, and the people in the north-east of Siberia, so strongly resembling the Esquimaux in language, *physique*, and customs, may have been American emigrants; but the reverse hypothesis appears to us much more probable.

Another extremely interesting paper by Mr. Markham, on the Arctic Highlanders, contains many details concerning the country, the character, the manners, customs, language, &c., of this curious people. Mr. Markham remarks upon what has been noticed by several explorers, the wonderful talent of this people for topography, and reproduces a most careful and accurate chart of the Greenland Coast from Cape York to Smith Channel, drawn by the Greenlander Erasmus York. These two papers are well worthy the attention, not only of the explorers for whom they have been compiled, but of all interested in Greenland ethnography. Mr. Markham's other contributions are a sketch of the grammar of the Esquimaux language, with copious vocabularies, and a long list of the names of all places on the coast of Greenland from lat. 65° 15′ N. on the eastern side, round Cape Farewell, to the entrance of Smith Sound. Along with this most laborious list is a chart of the south coast of Greenland from the Danish Admiralty Survey, with Mr. R. H. Major's adaptation of the ancient sites in the East Bygd, of the old Greenland colony.

Dr. Rink's paper on the Descent of the Esquimaux we have already referred to, and we have space merely to allude to the admirable and interesting and almost exhaustive paper on the Western Esquimaux, by Dr. John Simpson, of H.M.S. *Plover*, reprinted from the Parliamentary Arctic Papers of 1855. The volume concludes with the Report of the Anthropological Institute, and an appendix containing ethnological questions for explorers, drawn up by various eminent members of that Society.

Altogether, from the brief glance we have been able to take at this "Selection," it will be seen that it contains much of really intrinsic value, for having put which into so accessible a form, all who take an interest in Arctic matters will be grateful to the Geographical Society. It will, we are sure, moreover, be a welcome addition to the equipment of the members of the Arctic Expedition; and if carefully studied, as no doubt it will be, it cannot but suggest many lines of inquiry that are likely to lead to very valuable results.

VOGEL'S "LIGHT AND PHOTOGRAPHY"

The Chemistry of Light and Photography in its Application to Art, Science, and Industry. By Dr. Hermann Vogel, Professor in the Royal Industrial Academy of Berlin. With 100 Illustrations. (London: Henry S. King and Co., 1875.)

TO one acquainted with the very small amount of scientific literature yearly produced by the professional and amateur devotees of photography the name of Dr. Hermann Vogel is one associated most intimately with the scientific progress of the art. Dr. Vogel has lately attracted somewhat wider notice by his researches on the effects of coloured media in modifying the action of monochromatic light on photographic films, and the research is likely to lead to important results in the department of spectrum photography.

It was therefore in anticipation of at last finding a scientific manual of photography that we took up the translation of Dr. Vogel's work at present under review, hoping that Messrs. King and Co. had been the means of bringing a good book before the English scientific and photographic world. Unfortunately the whole experiment has been spoiled by the simple device of placing the translation in the hands of a person who is totally unacquainted with either chemistry or photography, and who is also not given to expressing himself in clear English.

On p. 4 we are informed that argentic chloride can be prepared by "directing chloric gas upon metallic silver;" and on p. 19 that "by employing *iodide of bromium* . . . the process of exposure was made a matter of seconds." On p. 35, "Archer coated glass plates with collodion in which salts of iodide had been dissolved;" and the same page contains this typical specimen of English: "After 1853 paper pictures on collodion negatives came more and more into vogue, the demands for daguerreotypes fell off and soon vanished altogether, and were produced only here and there in America;" while on p. 36 we are told that there are in Berlin "ten photographic album manufactories, to satisfy the demand, from whence they are exported to all parts of the world."

The following explanation of the reaction occurring during the immersion of the collodionised plate in the nitrate bath is given at p. 41: "The salts of iodine and of bromine that exist in the collodion film change their *properties* with nitrate of silver and give birth to iodide and bromide of silver and to *nitric acid salts*." The italics are our own. On p. 70 a footnote is added to explain that "1 gramme = the 1,000th part of a cubic metre, about nine solid feet of water at the ordinary average temperature."

Under the head of "Operation of Light on the Elements," which commences on p. 107, we find that chlorine is "a greenish strong-smelling gas developed from chloride of lime," that bromine "is an unpleasantly smelling substance of a fluid nature," and that iodine is "a black substance also of a fluid nature and used for friction." "Sulphur unites with oxygen and produces the pungent strong-smelling sulphuric acid;" "chloride and bromide gas show a peculiar relation to light even in their combinations;" and lastly, iodine again appears as a "solid body appearing in the form of shining black crystals, and emitting, when heated, a wonderful violet vapour."

Under the head of "Chemical Effects of Light on Salts of Silver," chloride of silver forms a "cheesy" precipitate; chloride, bromide, and iodide of silver are "very tenacious bodies;" when chloride of silver is exposed to light, the "chloride is liberated, and disappears as a greenish gas, which, from its abundance as well as its odour, can be perceived to be chloride of silver." "Green vitriol is greatly attracted by oxygen, and taking it up readily, passes into sulphate of iron."

On p. 118 we have the following lucid description of the toning process:—"The positive prints are subjected to a further treatment styled the colouring process. To this end it is plunged in a very diluted solution of gold. This solute (*sic*) contains chloride of gold. Metal silver has more affinity with chlorine than gold; hence it combines with the chlorine, forming chloride of silver, while the gold is precipitated. It becomes separated in the shape of a blue colour, adhering to the outlines of the picture, and this blue, mixed with the brown of the picture, gives a pleasant tone which does not change in the fixing-bath, that is, in hyposulphite of soda." The latter body is, by the way, alluded to indifferently as hyposulphite of soda, "fixing sodium," and "fixing natrium."

In photographic apparatus the translator is equally at sea. A dark slide is continually spoken of as a "cassette," and a printing frame as a "copper frame." The technical names of the processes are also as a rule incorrect.

We have no patience to devote more time to this wretched translation, which is only passable in portions of the part on the physics of some of the photographic processes.

While Dr. Vogel is held to blame for a prolixity and discursiveness which, together with the childishly elementary character of much of the work, render it very dull, the editors of the "International Scientific Series" must be held responsible for still further reducing the value of the work by employing a translator ignorant of the subject.

R. J. F.

OUR BOOK SHELF

Ornithological Miscellany. By George Dawson Rowley, M.A., F.Z.S., Member of the British Ornithologists' Union. Part I., No. I. January 1875. (London: Trübner and Co.)

THE first number of Mr. Rowley's "Ornithological Miscellany" is devoted to the illustration of some of the rarer birds of New Zealand which have lately come into his collection. The most interesting of these is perhaps the large spotted Apteryx discovered by Mr. Potts in 1873, and named after Dr. Haast, of which, we believe, Mr. Rowley's specimens are the first that have reached this country. Figures of and remarks on the other known species of Kiwi are also given, so that we have altogether a nearly complete account of what has yet been ascertained respecting the external form and habits of these singular birds. Mr. Rowley passes on to discuss the structure of the feathers of the Struthious birds, of which he also gives us some admirable illustrations. A glance at these will serve to show how very far removed in many essential points is the genus *Apteryx* from the Cassowaries and others of the order *Struthiones*, with which it is commonly associated. Finally, Mr. Rowley gives us an account of a white variety of one of the Nestor parrots of New Zealand, which, as all birds are subject to the occasional influences that produce albinism, is not, perhaps, after all, of special interest; but Mr. Keuleman's well-drawn figure of this bird will be appreciated by all ornithologists.

Such are the contents of Mr. Rowley's first number. In regretting that he does not know when the next will appear, or what it will contain, we fully sympathise with the author. But if Mr. Rowley can produce from his cabinets a similar series of rarities to figure, and find an equally good artist to draw them, we are sure that his second and following numbers will meet with equal appreciation from every lover of natural history.

On Numerals in American Indian Languages, and the Indian Mode of Counting. By J. Hammond Trumbull, LL.D. (Hartford, Connecticut, 1875.)

FROM a careful examination of the numerals in various North American languages, Dr. Trumbull adds some interesting evidence to that already available as to the native development of arithmetic among uncultured races. The derivation of numeral-words from the names of the fingers habitually used in counting numbers is well shown in Hudson's Bay; Esquimaux *eerkitkoka* = "little finger" being used as a numeral for 10, while *mikkeelukkamoot* = "fourth finger" signifies 9. Other materialistic sources of numeral-words are apparent in the Micmac language, where *tabu* = "equal" has become a numeral for 2 (like our own word "pair," from Latin *par*), while *tchicht*, which means 3, may have originally meant "more" or "again," and been used to distinguish the plural as beyond the mere dual (compare Latin *trans* and *tres*). As in the civilised Old World languages with which philologists especially occupy themselves, the numerals have for the most part lost the traces of their original significance, their development, a not unimportant part of the intellectual development of mankind, has to be learnt from investigations like the present into savage or barbarian tongues.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

British Rainfall, 1874

I AM much obliged by your favourable mention (NATURE, vol. xii. p. 76) of my annual volume, and am very glad to find that it concludes with a suggestion, because, to quote from p. 138 of

the work under notice, "We always receive with pleasure suggestions for the improvement of this publication, and within reasonable limits never allow either trouble or cost to prevent the adoption of all which in any way commend themselves to our judgment."

Your suggestion is as follows:—

"The publication of the monthly as well as the annual amounts of rain for the whole of the 1,700 stations is very desirable, and it is hoped that in an early issue of the 'British Rainfall' it will be done."

I shall be glad if you will allow me to supplement the data which were before you when the above paragraph was written by some other facts, and to learn from your pages whether or not this fuller information induces any modification of your views.

As I (whether fortunately or unfortunately I need not say) have to pay my own printer's bills, I always keep them as low as possible; hence, the publication being an annual one, statements made in one volume are rarely repeated in the next. Therefore, probably, your reviewer was not aware of the principles upon which the tables of monthly rainfall (pp. 140–145) are compiled, viz., to give one station in every county in the British Isles, and two in a few of the larger ones, such as York, Inverness, and Ross. I may add *en passant* that these tables give the monthly fall at 108 stations, while the Registrar-General of England is satisfied with forty-four, and of Scotland with fifty-five; so that my table exceeds both together. That, however, is of little moment. [For your own information, I enclose a map with these 108 stations plotted.]

In the next place, I must refer to "British Rainfall, 1871," pp. 135–138, where the question of publishing additional monthly returns is discussed at length, and the method of computing the monthly fall from the percentage tables (which are given every year) is explained and illustrated by a completely worked-out example.

To this let me add that returns from 150 other stations are published monthly in my *Meteorological Magazine*, and that up to the present time another very large series (143) has been printed biennially in the Reports of the British Association.

If it is the opinion of yourself and of others competent to judge that still more is necessary, more shall be done; but it must be borne in mind that the accurate (and without accuracy figures are worse than useless) printing of 20,400 values involves a great expenditure both of time and of money. I do not quite know whence either the one or the other is to be obtained.

G. J. SYMONS

[It was just because of the inadequacy of one station in each county of the British Isles, and two in the larger counties, to represent the rainfall, even though these be supplemented by Mr. Glaisher's forty-four stations, the Scottish Meteorological Society's two hundred odd, and by Mr. Symons himself in his Magazine and in the British Association Reports, that we stated it to be very desirable that the monthly as well as the annual amounts of rain for the whole of the 1,700 stations were published. The method of computing the monthly fall from the percentage tables referred to in "British Rainfall, 1871," pp. 135-138, does not supply what is desiderated. It is the capriciousness of the distribution of the rainfall and its important bearings on many practical questions which render so desirable a knowledge of the actual monthly amounts in particular localities. Since what is desired would be an invaluable contribution to British Meteorology, we earnestly hope that Mr. Symons will be induced to supply it, and that in that case he will receive substantial support in carrying on a work so important.]

Equilibrium of Temperature in a Vertical Column of Gas

I OBSERVE that Mr. R. C. Nichols, in his letter to NATURE (vol. xii. p. 67), admits that the mean energy of molecules "*may*" remain the same at all points of a vertical column. It is not difficult to show that it *must* do so if the velocities are distributed among the molecules according to the exponential law.

As I have never seen any direct proof of this in English I extract the following from Boltzmann.

In order not to take up too much of your space, we will take the simplest case, and suppose the molecules to be equal elastic spheres, moving in a vertical tube with elastic base and sides. Let them be acted upon by vertical forces, the potential of which at height x above the base is $f(x)$. Assume first that no encounters take place between the molecules, and let the number of molecules at the base, the energy of whose vertical velocity is v^2, be $C\epsilon^{-\frac{v^2}{k^2}}$ where C and k are constants. For each molecule the sum of the potential and kinetic energies is constant.

And as the horizontal velocities are constant, it follows that for each molecule the sum of the potential energy and the energy of vertical velocity is constant. That is, the energy of vertical velocity is diminished by $f(x)$ in the ascent from the base to x.

Therefore the molecules which at height x have u^2 for energy of vertical velocity are the same identical molecules which at the base have $u^2 + f(x)$ for energy of vertical velocity.

Their number is therefore $C\epsilon^{-\frac{u^2+f(x)}{k^2}}$ that is $\epsilon^{-\frac{f(x)}{k^2}} C\epsilon^{-\frac{u^2}{k^2}}$.

Therefore the number of each class at x is the same as the number of the same class at the base multiplied by the factor $\epsilon^{-\frac{f(x)}{k^2}}$

Evidently the mean energy is the same at all points of the tube, and the density only varies, and is represented by $\epsilon^{-\frac{f(x)}{k^2}}$.

Again, still precluding encounters, let the velocities of the molecules in each of two horizontal directions at right angles to each other be distributed according to the same law as the vertical. And further, let the chance of a molecule having given horizontal velocity in either direction be independent of its velocity in the other horizontal direction or in the vertical. The same distribution and independence will be maintained throughout the tube. And we see that force has no tendency to disturb it.

Maxwell has shown that among such molecules as we have supposed encounters have no tendency to disturb the given distribution, which must therefore remain undisturbed though force and encounters both be present.

S. H. BURBURY

Primine and Secundine

WILL you allow me to avail myself of your pages as a means of pointing out to those who have purchased the English edition of "Sachs's Text-book of Botany" an unfortunate error which Prof. Oliver has been so good as to point out to me?

On p. 501 the inner coat of the ovule is identified with the "Primine" of Mirbel, and the outer with the "Secundine." The application of these terms is exactly inverted. The confusion easily arises from the fact that the secundine is developed *first* and the primine *second*. Mirbel, however, ignorant of, or disregarding that fact, numbered his structures from without inwards. The outer coat he termed the primine, the inner the secundine, the nucleus the tercine, and so on to quartine and quintine.

Except for the sake of accuracy the matter is of no essential consequence. Those who study the coats of ovules may well be indifferent to Mirbel's perplexing terms. But in these days, when students are expected for examination purposes to know about the names of things rather than about things themselves, it might lead to deplorable consequences, of which I hasten to relieve myself of the responsibility.

W. T. THISELTON DYER

American Indian Weapons

IN Col. Lane Fox's Catalogue of his Anthropological Collection he quotes Schoolcraft as saying, "There is no instance amongst the North American Indians in which the war-club employed by them is made of a straight piece, or has not a curved head." I send you a drawing (Fig. 1) of a club in common use among the Numas, or Indians of the Great Interior Basin, embracing Shoshones, Utes, Pueblos, &c., which will no doubt interest Col. Fox and others, not only on account of its extreme simplicity of form, but also of its method of use. It might be called appropriately a "face-masker," being grasped with the bulb next to the little finger, and thrust into the countenance of the foe. Major Powell sent a number of these to the Smithsonian Institution. They are of one piece of wood, generally mezquite, either very rude or quite smoothly polished, and are worn attached to the wrist by a leather thong. They vary in length from eight inches to fourteen. These same tribes use a simpler "slung shot" than the one described in Col. Fox's Cata-

logue, p. 65 (Fig. 2), the stone ball hanging loosely from the handle in a bag of buckskin. The Moquis of this same region use the boomerang; two of these (Fig. 3) are in the Smithsonian Institution. I am not sure that it returns to the hand of the thrower.

On page 91 of Col. Fox's Catalogue he says: "In California

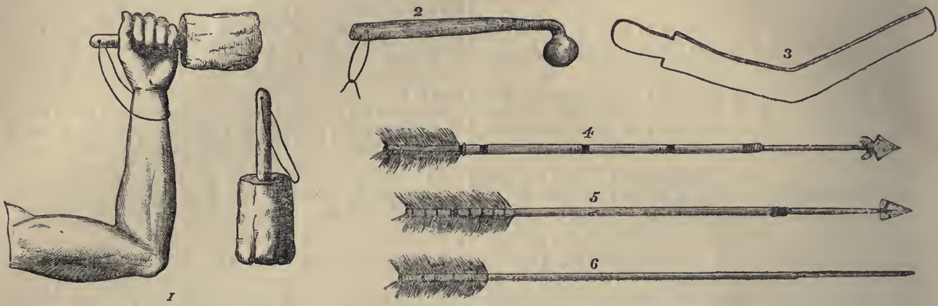

Fig. 1.—Pai-Ute War Club, for thrusting by a backhanded blow into the face of an enemy. Made from the wood of the Mezquite bean.

Fig. 2.—Pai-Ute War Club. Fig. 3.—Moquis Boomerang. Fig. 4.—Numa Reed Arrow, with hard wood foreshaft. Fig. 5.—Klamath River Pointed Arrow; soft wood shaft, hard wood foreshaft. Fig. 6.—Klamath River Arrow, without point; soft wood shaft, hard wood foreshaft sharpened.

and the greater part of the North American Continent the arrows are constructed either in a single piece or with a bone foreshaft; but in no case have I come across a foreshaft of hard wood." Among the Numas of the Great Basin, reed arrows with hard wood foreshaft are very common (Fig. 4). In Northern California two kinds of arrows have hard wood foreshaft, those with and those without stone points (Figs. 5 and 6). The stripes on the feather end are rancheria marks, and the foreshaft is moveable.

Primroses and Cowslips

MR. FORDHAM (NATURE, vol. xii. p. 87) is quite right in conjecturing that it may be without foundation he has thought that primroses are not found in districts in which cowslips are common, and *vice versâ*. In the north-east of Staffordshire, for miles round Denstone College, early in the spring, nearly all the hedges and many of the fields are covered with primroses. Later on cowslips abound; I might add that oxlips are also far from being rare.

I have watched closely, but have never found a trace of any destruction of the flower by birds. This, perhaps, may be accounted for by the fact that this being a pasture country, the sparrow, finding no grain, is a *rara avis* about here. I have noticed in Lord Bagot's wood, some twelve miles from here, where sparrows as well as many other birds are found in great numbers, that the primroses nearly always present a very ragged appearance.

D. EDWARDES

Denstone College, Uttoxeter

I COULD name half a dozen spots to the north of London (Mill Hill) where cowslips and primroses have abounded together in the same meadow, to my own knowledge, for the past twenty years. For at least five years I can say that neither the primroses nor cowslips were attacked by birds, though the crocuses were cut up by them more or less every season in the same locality.

R. A. N.

THE VISITATIONS OF GREENWICH AND EDINBURGH OBSERVATORIES

WE have before us the Annual Reports of the Astronomers Royal for England and Scotland, to their respective Boards of Visitors. The Report of Sir G. B. Airy consists mainly of the usual statements under the various heads of the state of the buildings and instruments, the constitution of the staff, and the amount of work done. In all these respects the Observatory seems to be in a satisfactory condition. One important change in the staff during the past year has been the resignation of Mr. Glaisher, who has for so many years been connected with the Observatory, and which has rendered necessary a readjustment of the duties of the various observers.

Under the head of "Chronometers, Time-signals," &c., the Astronomer Royal refers to the supplemental mechanism which he himself has introduced into some chronometers in order to correct the perceptible defect of thermal compensation which occurs in nearly every case, even in the best chronometers. "There is," he states, "great difficulty in correcting the residual fault, not only because an inconceivably small movement of the weight on the balance-curve is required, but also because it endangers the equilibrium of the balance. To remedy this I have introduced small supplementary weights carried by means of a supplementary bar (rotating with stiff friction in the balance-staff), at whose ends are very light springs carrying the supplementary weights, and constantly pressing them to the interior of the balance-curve. When the supplementary bar is so turned that the supplementary weights are near the end of the balance-curve, the compensation is large; when they are near the root of the balance-curve, it is small. The movement from one state to the other is so simple that probably an assistant of the Observatory will be able to manage it, and it does not interfere with equilibrium. This arrangement has received the approval of some able chronometer-makers, and may perhaps with advantage be adopted generally."

The various time-signals and clocks connected with the Observatory have been worked with praiseworthy regularity and accuracy; the Westminster clock has been so well regulated, under check of automatic report to the Observatory, that in 83 per cent. of the days of the year its error is below one second. Proposals have been made for galvanic determination of the longitude of the Dublin Observatory, and the operation is delayed only for convenience in the arrangements to be made at Dublin. With the aid of a grant from the Treasury three computers are now steadily at work on the Astronomer Royal's New Lunar Theory.

The most novel and interesting part of Sir George Airy's Report is his concluding "General Remarks," in which

he takes a rapid glance over the changes in the Observatory in the forty years during which he has been at its head. "The Observatory was expressly built," he states, "for the aid of astronomy and navigation, for promoting methods of determining longitude at sea, and (as the circumstances that led to its foundation show) more especially for determination of the moon's motions. All these imply, as their first step, the formation of accurate catalogues of stars, and the determination of the fundamental elements of the solar system. These objects have been steadily pursued from the foundation of the Observatory; in one way, by Flamsteed; in another way, by Halley, and by Bradley in the earlier part of his career; in a third form, by Bradley in his later years, by Maskelyne (who contributed most powerfully both to lunar and to chronometric nautical astronomy), and for a time by Pond; then with improved instruments by Pond, and by myself for some years; and, subsequently, with the instruments now in use. It has been invariably my own intention to maintain the principles of the long-established system in perfect integrity; varying the instruments, the modes of employing them, and the modes of utilising the observations by calculation and publication, as the progress of science might seem to require.

"While instruments of the same class, but of increased power, have been substituted for those which I found here, three novel constructions have been introduced; the lunar altazimuth, the reflex-zenith-tube, and the chronograph; and, for a special investigation, the water-telescope (now dismounted). I omit mention of auxiliary instruments. To utilise the observations, the numerical reductions for each current year have always been maintained in the most perfect state that I could devise. From these, elaborate star-catalogues (now in frequent demand) have been formed from time to time. And, for connecting the observations of the moveable bodies of our system in a complete and homogeneous series, beginning at 1750, first the planetary observations, and secondly the lunar observations of my predecessors have been reduced, and orbital elements have been corrected. The lunar reductions are probably the greatest single work ever undertaken in astronomy. This portion of our labours may be considered as applying to the combined subjects of astronomy and navigation. But there are also, peculiar to astronomy, the photoheliography and spectroscopy lately introduced. And, peculiar to navigation and related subjects, there are the investigation of the laws of magnetic disturbance in iron ships, and the correction of the compass by methods now used in the commercial navies through the world; the maintenance of magnetic observations; the incessant attention to chronometers; the extensive dissemination of accurate time-signals; and the daily dropping of a time-ball at Deal.

"The subject of meteorology, which has been followed for many years, is scarcely connected with the two great heads of astronomy and navigation, and hardly deserves the name of a science. It is, however, in great popular request. Mechanical self-registration of some meteorological phenomena was introduced by me shortly after the commencement of my residence. Since that time the practical arts of photography and galvanic communication were invented, and they were quickly made available in many of our operations. In this increase of occupations, the annual expenses of the Observatory have increased, but in a much lower proportion than the work done.

"Experiments have been made, bearing on cosmical physics, by Maskelyne for the attraction of Schehallien, and by myself for the vibrations of pendulums in mines. Preparations have been made for observations of eclipses and of the Transit of Venus. Assistance has been rendered to the Government in training officers for such services as tracing national boundaries, &c., and in reference to National Standards. The Lunar Theory, though most intimately connected with the highest interests of astronomy, scarcely presents itself to me as a work of the Observatory.

"Turning now from the past to the future, I see little in which I could suggest any change. If it should ever be necessary to make any reduction, I should propose to withdraw meteorology, photoheliography, and spectroscopy; not as unimportant in themselves, or as ill-fitted to the discipline of the Observatory, but as the least connected with the fundamental idea of our establishment. In the nature of addition, I will indicate one practical point. I much desire to see the system of time-signals extended, by clocks or daily signals, to various parts of our great cities and our dockyards, and above all by hourly signals on the Start Point, which I believe would be the greatest of all benefits to nautical chronometry. Should any extension of our scientific work ever be contemplated, I would remark that the Observatory is not the place for new physical investigations. It is well adapted for following out any which, originating with private investigators, have been reduced to laws susceptible of verification by daily observation. The National Observatory will, I trust, always remain on the site where it was first planted, and which early acquired the name of 'Flamsteed Hill.' There are some inconveniences in the position, arising principally from the limited extent of the hill, but they are, in my opinion, very far overbalanced by its advantages."

We quite agree with the Astronomer Royal that a strictly Astronomical Observatory is not the place for such observations as those mentioned in the conclusion of his Report; it would be much, both to the advantage of astronomy and of the important branches of science referred to, that the latter should have one or more Government establishments allotted solely to their investigation, establishments quite distinct from and independent of the Greenwich Observatory.

The Report of the Astronomer Royal for Scotland is a little more fervid than the one just mentioned, or indeed than official documents generally are. The funds of the northern establishment continue to be extremely inadequate to its requirements, and it reflects great credit on Prof. Piazzi Smyth that he is able, year after year, to show such a satisfactory output of work.

In reference to Zodiacal Light Spectroscopy, the Report, referring to the results obtained by the expedition, at Prof. Smyth's own expense, to Sicily in 1872, states that he has another research of the same kind in progress, which will require him, for its completion, to visit successively with the same instruments the shores of the Arctic Ocean and a tropical mountain-peak. We hope Government will provide him with the very small sum necessary to carry out this important work. Prof. Smyth is also carrying out, under great difficulties, observations in Auroral Spectroscopy, for which he is very favourably located; but again he is hampered by want of the necessary instruments. No doubt Mr. Cross's recent unexpected official visit, if it meant anything at all, will lead to speedy attention being paid to the very reasonable demands of the Scottish Astronomer Royal.

An appendix to the Report contains some documents intended to show the real position of the Observatory and of its chief, and his relation to the professorship of astronomy in Edinburgh University which he holds. It seems the University Council wish to make out that 300*l.* of his not excessive salary he receives solely as occupant of that chair, and must resign this sum with the chair. Altogether it seems to us the duty of Government to make a speedy and thorough inquiry into the position of the Northern Observatory, and put it into a state of such complete efficiency that there will be no further room for complaints. We regret to see that the new equatorial is still in the contractor's hands.

THE PROGRESS OF THE TELEGRAPH *

VII.

IN 1843 Alexander Bain made certain important improvements in the recording and transmitting instrument shown in Fig. 28, in which two semicircular magnets B B′, with similar poles facing, fixed to a brass bar, move through the centres of two coils, A A′, the index-hand pointing to I or V according to the direction of the current. This was controlled by the metallic contacts N N′ N″ N‴ opening or closing the battery and line circuits according to the position of the handle F. The connection and direction of the current through the instrument from the battery D is indicated by the arrows, the connection R being that of the line wire, and S that of the earth circuit.

This patent and certain others that will be brought under notice gave rise to expensive litigation in the early history of the telegraph. In 1846 John Nott produced his letter-recording telegraph, which, in conjunction with Mr. Alexander Bain's inventions, was carried into the law courts on a question of infringement of the Cooke and Wheatstone patent rights; but for reasons already given regarding patent law, the opposition was unsuccessful on the part of the Electric Telegraph Company.

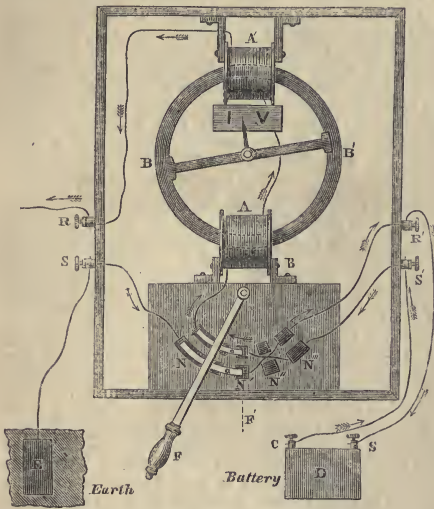

FIG. 28.—Bain's I and V telegraph, 1843.

Nott's apparatus is shown in external and internal elevation in Figs. 29 and 30. It consisted of a dial showing the letters of the alphabet and numerals repeated four times in the circumference of the circle. The respective letters or numerals were indicated by the step-by-step motion of a revolving pointer or index-hand. The motion of this pointer was controlled by successive make-and-break contacts with the battery by means of a finger-key dipping into a mercury cell, *b*. The index-pointer was driven round by a "clawker-and-driver" action in connection with the toothed wheel *c*, the propelling power being derived from the attractive and repellant action of two horseshoe electro-magnets, *a*, *d*, acting upon soft iron armatures in connection with the "clawker-and-driver" motion. The electro-magnet *b* governed the alarum or call-signal. Either the speaking or alarum portion of the telegraph was brought into action by the position of the contact drums, *f*, *f*, which regulated the direction of the battery current through the electro-magnets, by means of the index shown in the external view (Fig. 29) being moved to the one side or the other.

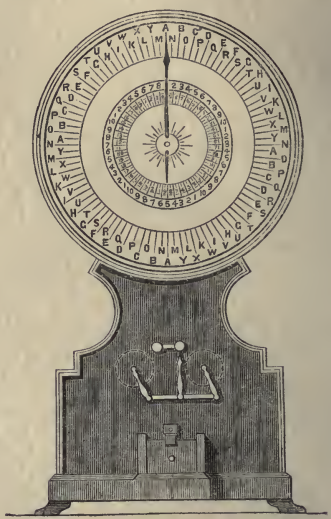

FIG. 29.—Nott and Gamble's patent, 1846. External view.

In 1846 Highton's gold leaf indicator was brought under notice, and an important automatic chemical printer-recording high-speed telegraph, by Alexander Bain, which has been the germ of several of the applications in the modern high-speed automatic arrangements (Fig. 25). In this chemical printer, a paper strip, perforated with holes in symbolic groups to represent the several words of the message, was employed to regulate the automatic sequences of the current through the line. This paper ribbon was passed over a metal drum in circuit with the line wire, and a fine metal style in connection with one pole of the battery

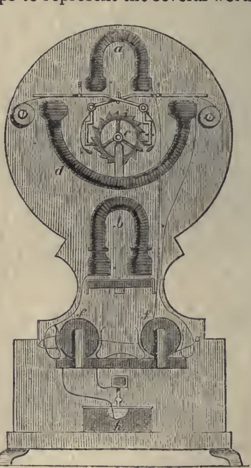

FIG. 30.—Nott and Gamble's patent, 1846. Internal arrangement.

* Continued from p. 72.

(the other pole being to earth) pressed upon the paper ribbon. As the ribbon was drawn forward whenever a perforation passed the point of the style, metallic contact between the battery and line wire was momentarily made, and a current transmitted to the distant station, the duration of the current being regulated by the length of the perforation in the paper—thus giving the dot and dash code. The message at the distant station was printed by chemical decomposition. A ribbon of paper, prepared by immersion in a solution of sulphuric acid and prussiate of potass, was drawn over a metal cylinder in communication with the earth, and pressing upon this chemically prepared paper was a metal style in connection with the line wire. When, therefore, a current is received by reason of the metal style at the transmitting station passing a hole and joining battery to line, the chemical preparation of the receiving ribbon is momentarily decomposed by the action of this current, and a darkish blue mark will appear on the paper ribbon of a length—either a dot or a dash—corresponding to the duration of the transmitted current.

William Sykes Ward's patent, by which signals were indicated by the deflection of electro-dynamic coils over the poles of fixed permanent magnets, already noticed (Fig. 18), followed in 1847. This patent became, in common with most others, the property of the Electric Telegraph Company by purchase.

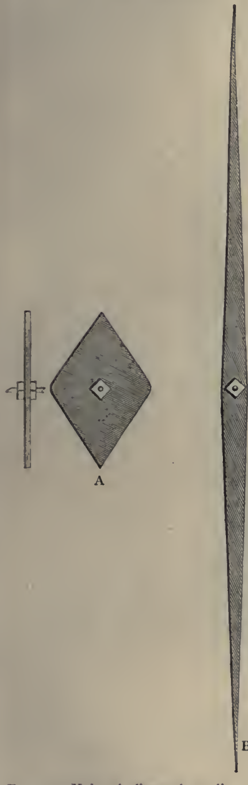

Fig. 31.—Holmes' diamond needle arrangement (A), dispensing with the astatic needle combination (B) and reducing the resistance of the coils. 1848.

Holmes's new form of coil and needle, introduced in 1848, dispensed with the inertia of the long five-inch astatic needle combination and great coil resistances of the existing double needle system, and combined a greatly increased speed of transmission with a reduced battery power, both results of vital importance. This modification of the astatic needle combination is shown at Fig. 31, drawn to actual size, as compared with the five-inch needle.

The next patent brought under notice, that of Mr. W. T. Henley, led to the first serious opposition against the monopoly of the Electric Telegraph Company. In 1848 William Thomas Henley and George Foster brought out their improvements in electric telegraphs: this patent gave rise to the formation and establishment of a formidable rival in public favour to the Electric Telegraph Company, viz., the English and Irish Magnetic Telegraph Company. The improvements under this patent consisted in acting on a magnet, to the axis of which is attached an index or pointer by a single electro or other magnet, having each of its extremities converted or resolved into two or more poles. Fig. 32 shows the magnetic needle suspended between the poles of an electro-magnet, *a*, each pole being fitted with a piece of iron, of a segmental form, developing two similar poles. This magnetic needle is deflected in one direction for any length of time required by an induced magneto-current, it being brought back to its normal position by the reversed inductive current. The necessary magneto-currents to actuate the needle are produced from a magneto-electric arrangement consisting of two coils, A, A (on an armature), which are mounted on an axis, H, between the poles, M, M, of a permanent-magnet, and free to move in front of those poles upon depression of the handle, G, in such a manner that one pole of the magnet is not released from its opposition to the armature until the other just touches it, by which means currents of equal power and in opposite directions are produced. This arrangement of parts is shown in Fig. 33. These several representative improvements, selected out of the vast numbers that crowd the field up to 1848, will be sufficient for the purpose of tracing the Progress of the Telegraph.

Such were some of the instruments already invented when electrical communication was inaugurated in this country by the Electric Telegraph Company.

Proceeding down the *cul de sac* known as Founders Court, Lothbury, a stone façade, with the words "Central Telegraph Station" sculptured in bold letters, and massive oak doors, arrested the attention of the visitor. On entering, a noble and lofty hall with an enriched glass roof presented itself to view, with two long counters, one on either side, for the receipt and payment of messages. Behind these counters glass screens were placed with the names of the several stations open for messages painted in black letters upon them, the instrument rooms being behind the screens upon either side.

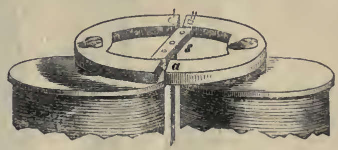

Fig. 32.—Henley and Foster's Magneto-Telegraph, 1848. Indicator movement.

The west side of the hall was devoted to correspondence with the northern and western districts, and the east side with the eastern and southern districts. Additional instrument rooms were provided on the first and second floors at the sides of the hall; and at the time of the opening of the station to the public, the Company had access to about sixty towns, with an extent of single wire along the railways of some 2,500 miles, and had a telegraph staff of fifty-seven hands appointed to the Metropolitan Station. The battery rooms, testing boxes, earth connections, and the tubes for bringing the wires into the building were situated in the basement underneath the great hall. The various wires were brought along the streets in pipes beneath the pavement. Twenty-seven came from the North Western Railway, nine from the South Western, nine from the South Eastern, nine from the Eastern Counties, nine from the branch office, 345, Strand, including those from Windsor, nine from the Admiralty, which with nine spare wires completed the circuit arrangements of the Company at the time that the telegraph was thrown open to the public. Many of the railway companies continued to reserve the use of their telegraphic lines to themselves; the Telegraph Company from the central station had therefore no power to forward public messages over such districts.

It is natural to suppose that great excitement and anxiety existed amongst the directors with reference to the opening of the building to the public for the receipt and transmission of messages. The disturbed state of

London at that time, arising from the Chartist demonstration and supposed possible attempt upon the Bank of England, by no means allayed the disquietude of the directors; as it was, most of the electrical staff had been sworn special constables, and truncheon in hand had assisted in guarding the principal buildings in the vicinity of the Bank of England and Royal Exchange. What if on the opening day a mob should rush in intent upon destroying the new-fangled invention! Such occurrences had been witnessed before. Had not Arkwright with his stocking loom, and Jacquard, incurred the fury of the ignorant artisans? Might not the rush of relatives and friends, merchants and bankers, all anxious to supersede the delays of post by the lightning speed of this new invention laid at their feet for the first time, prove so inconvenient to the clerks that all business would be interrupted, and the accuracy of the payments for messages and correctness of the transmissions be jeopardised? Besides, another evil rumour had gone abroad: light sovereigns and indifferent gold were in free circulation. Amongst all these troubles it is not to be wondered at, that as the eventful day drew near every precaution was taken to meet the assumed exigency of the occasion; sovereign scales were ordered, one for each counter already described. How could a clerk leave his place of trust to weigh a suspicious-looking piece of gold in scales situated on the opposite side of the great hall? The uniform shilling rate to all places from the metropolis did not at that time exist. Messages to Liverpool and Manchester were 8*s.* 6*d.* under twenty words, to Edinburgh 13*s.*, and to Glasgow 14*s.*; charges at that time considered very moderate, remembering the costly staff of clerks, the original outlay, wear and tear, &c. The great doors in Founder's Court were ordered to

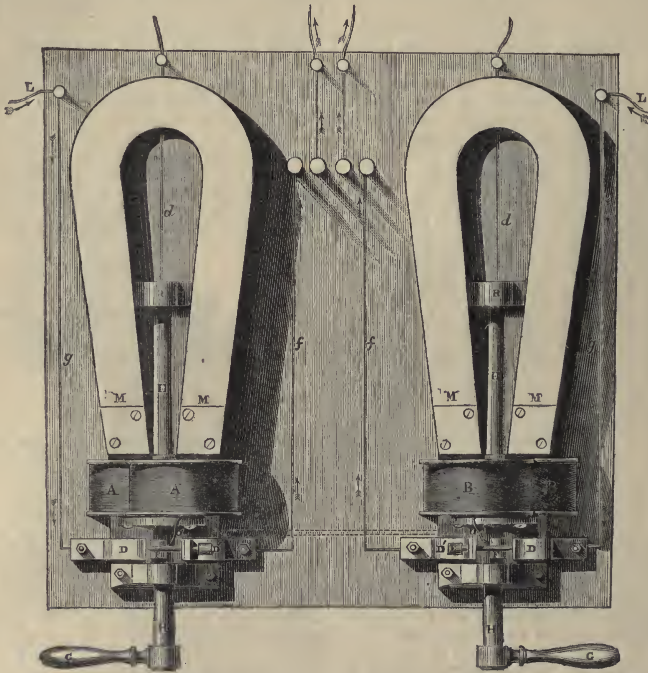

FIG. 33.—Henley and Foster's Magneto-Electric Telegraph, 1848. Plan of the magneto-coil arrangement for producing currents of equal intensity in opposite directions.

be kept fast bolted, and two port-holes cut some six inches square in the solid oak panels fitted with little screens opening inwards; so that whatever the crush in Founders Court, messages and money could be received inside through them and change given; in fact, the Central Telegraph Station was converted more or less into a fort prepared to stand a siege. The opening day came—scales on counter, change in tills, receiving and cashing clerks at their posts, every instrument and circuit along the respective railway lines proved for accuracy by the sending and receipt of test signals, staff at instruments, doors bolted. Nine o'clock strikes, port-holes opened, and, after the manner of the stage manager behind the curtain who surveys the patronage bestowed upon the boxes, stalls, and dress circle from his mysterious peephole, so did the expectant staff view the state of Founders Court through their port-holes. Not a person disfigured the symmetry of the lines of the flag pavement, save the Bank of England porter, performing his prescribed beat against the Bank wall. The sun marked midday,—afternoon,—evening,—and one paid message alone was transmitted to a station situated somewhere upon the Norwich circuit. Empty tills, idle clerks, disappointed directors. Such was the story of the opening day of the Electric Telegraph Company's Central Office. No one believed in it; it was regarded more in the light of a clever toy than a practical invention to be trusted or relied upon. This want of patronage from the public damped the ardour of some of the directors. The late Mr. Sampson Ricardo, walking into the central station the next morning, gave vent to his disappointment by declaiming on the extravagant expenditure of capital in two pairs of sovereign scales, demanding that one pair should be immediately returned to the scale-maker who had supplied the luxury.

After the vast expenditure of capital in the purchase of the Cooke and Wheatstone patents, erection of lines over the kingdom, station inauguration, and the incorporation of the Company by special Act of Parliament, naturally the promoters of the Electric Telegraph Company endeavoured to create a monopoly in the transmission of messages for the public.

(*To be continued.*)

OUR ASTRONOMICAL COLUMN

THE TOTAL SOLAR ECLIPSE OF 1886, AUG. 29.—This eclipse will be a remarkable one, on account of the length of duration of totality, which will not fall far short of that of the eclipse of 1868, Aug. 18, though it unfortunately happens that its track is mainly over the Atlantic Ocean, and there will be no land station for physical observations while the sun is hidden for the longest interval. The elements of the eclipse are, very approximately, as follows:—

Conjunction in R.A. 1886, Aug. 29, at 0h. 57m. 37·7s. G.M.T.

	°	′	″	
R.A.	157	50	51·9	
Moon's hourly motion in R.A.		37	4·8	
Sun's ,, ,, ...		2	16·7	
Moon's declination	9	10	38·4	N.
Sun's ,, ...	9	17	23·9	N.
Moon's hourly motion in Decl.		10	45·1	S.
Sun's ,, ,, ...		0	53·4	S.
Moon's horizontal parallax		61	20·5	
Sun's ,, ...			8·8	
Moon's true semidiameter		16	42·9	
Sun's ,, ...		15	51·1	

The central eclipse begins Aug. 28, at 23h. 12m. 32s. G.M.T., in longitude 79° 33′ W., and latitude 9° 51′ N., and ends Aug. 29 at 2h. 36m. 28s. in longitude 47° 19′ E., and latitude 21° 57′ S., and the sun is on the meridian centrally eclipsed in longitude 14° 13′ W., and latitude 2° 58′ N. The following are also points upon the central line:—

Longitude.	Latitude.
66° 47′ W	11° 36′ N
61 1 W	12 6 N
11 9 E	11 5 S
20 10	14 52
21 39	15 25
25 5 E	16 36 S

It would appear from this track that the only easily accessible station where the sun will be at a sufficient altitude will be at the southern extremity of the Island of Grenada, in the West Indies; for which point, assuming its longitude 4h. 6m. 20s. W. and latitude 11° 59′ N., we find—

	H. M. S.	
Beginning of totality, Aug. 28, at	19 10 7	Local
Ending ,, ,,	19 13 22	mean times.

The duration is therefore 3m. 15s., and the sun's altitude is about 20°.

If we take for a point where the sun will be near the meridian, longitude 0h. 50m. 52s. W. and latitude 2° 8′ N., we have—

	H. M. S.	
Beginning of totality, Aug. 29, at	0 8 48	Local
Ending ,, ,,	0 15 14	mean times.

The duration of total eclipse, which is here nearly at its maximum, is therefore 6m. 26s., and the sun at the time is only 7° from the zenith.

From this point the length of totality diminishes, until, during the passage of central eclipse over Southern Africa from near St. Philip de Benguela to the Mozambique, it is comparatively short. It will be seen that the central line runs considerably to the north of the islands of Ascension and St. Helena.

The middle of general eclipse occurs at 0h. 54m. 30s. G.M.T.; the sidereal time at Greenwich mean noon is 10h. 30m. 27s·8, and the equation of time 0m. 46s. subtractive from mean time, figures which may facilitate a further examination of the phenomenon.

THE SUN'S PARALLAX.—Prof. Galle, Director of the Observatory at Breslau, in a letter to M. Leverrier, gives the definitive result of his discussion of observations of the minor planet Flora (Hind, 1847, Oct. 18) in the autumn of 1873, at observatories in both hemispheres, with the view to a determination of the solar parallax. The receipt of particulars concerning some doubtful observations at Melbourne and other stations had enabled him to apply some small corrections, by which, however, the value of the sun's parallax published in No. 2,033 of the *Astronomische Nachrichten* is but very slightly changed. Prof. Galle now finds from eighty-one corresponding observations between the two hemispheres, forty-one stars of comparison to the north of the planet and forty to the south, that "the definitive result for the solar parallax should be fixed at $\pi = 8''{\cdot}873$, with a very small uncertainty in the hundredths of the second." He adds, that of ninety-six corresponding observations in all, he had excluded fifteen on account of some discordances arising from imperfections in the southern instruments, but even if these fifteen observations were included, the value is only changed to 8″·878. Prof. Galle is engaged in the composition of a memoir giving full details of his investigation. He remarks upon the close agreement of his result with that obtained by the numerous and very exact measures of the velocity of light, by M. Cornu, at the Observatory of Paris, with the theoretical determination of M. Leverrier from the perturbations of the planet Mars, and with M. Puiseux's first result from observations of the transit of Venus at Pekin and St. Paul Island. He directs attention to the circumstance, that another favourable opportunity of applying the method which has furnished a value for the sun's parallax by observations of Flora in the northern and southern hemisphere, so nearly in agreement with values deduced in other ways, will be afforded about the opposition of Eurydice (Peters, 1862, Sept. 22), which occurs on the 20th of September next, when the planet will be a bright ninth magnitude. It will be in perihelion early in the previous month, and at its nearest approach to the earth on Sept. 13, will be distant less than 0·878 of the earth's mean distance from the sun. Prof. Galle hopes to secure on this occasion the co-operation of the astronomers who have taken part in the observations of Flora.

THE MINOR PLANETS.—On comparing elements of this group as known to the present time, it appears that *Flora* has the shortest period of revolution, 1193 days, and of those which have been satisfactorily calculated, *Sylvia* has the longest, 2374 days, the corresponding mean distances, expressed in parts of the earth's mean distance from the sun, being 2·201 and 3·482. The nearest approach to the sun is made by *Phocea*, 1·787, while *Freia* recedes furthest from him, the aphelion distance being 4·002. We may add to these the following values near the extremes of distance:—

	Distance in Perihelion.		Distance in Aphelion.
Melpomene	1·796	Sylvia	3·757
Clio	1·805	Cybele	3·803
Victoria	1·823	Pales	3·810
Iris and Ariadne ...	1·835	Euphrosyne	3·849
Eurydice	1·854	Hermione	3·882
Flora	1·856		
Polyhymnia	1·890		
Virginia	1·899		

Polyhymnia has the greatest excentricity, 0·33998, and *Lomia* the least, 0·02176; *Pallas* the greatest inclination, 34° 42′, and *Massalia* the least, 0° 41′. It will be seen that the difference of distance from the sun between Phocea in perihelion and Freia in aphelion is 2·215, corresponding to about 204,000,000 miles.

M. Leverrier's *Bulletin International* of June 5 cor-

tains a telegraphic intimation from the Smithsonian Institution of the discovery of a new minor planet by Prof. Peters in R.A. 17h. 21m., and N.P.D. 113° 21′. It is as bright as stars of the eleventh magnitude, and is No. 144 of this group of planets.

[Since the above was in type we receive notice of the discovery of No. 145, by Prof. Peters, in R.A. 17^h 14^m, N.P.D. 113°·8′, apparently on June 4. Motion towards S.: twelfth magnitude.]

LECTURES AT THE ZOOLOGICAL GARDENS *

VI.—*Mr. Flower on Elephants.*

WITH the exception of the domesticated species few mammals are so well known to everyone as the Elephant, few are more interesting from their sagacity and usefulness to mankind, and few are so wholly separated and isolated from all other forms which now exist. Formerly the Elephants were grouped with the Rhinoceroses or with the Pigs, but a better knowledge of their structure has shown that they form an entirely distinct order, to which the name *Proboscidea* has been given, on account of the trunk, or proboscis, which is one of their most striking features. Two well-marked species of Elephant exist, the Indian (*Elephas indicus*) and the African (*E. africanus*).

The former is found in a wild state throughout the forest-lands of the greater part of India, Ceylon, Burmah, Siam, Cochin-China, the Malay Peninsula, and Sumatra, except where it has been driven back by the advance of civilisation; whether it is indigenous to any of the other islands of the Eastern Archipelago is doubtful. The Elephant of Sumatra and Ceylon has been separated by Schlegel as a distinct species, *E. sumatranus*, but Dr. Falconer and others have shown that their differences, though appreciable, do not amount to specific characters. The Indian Elephant has been domesticated from the earliest ages—in India before historic times, and also by the ancient Persians. It has been used in war, in carriage, and in state pageants, and is still much employed in road-making and bridge-building, where its strength, its sagacity, and its adroitness in piling logs, lifting weights, and similar operations, render its services invaluable.

The second species inhabits Africa, south of the Sahara, from the Indian Ocean to the Atlantic, and formerly extended its range to the Cape of Good Hope. In ancient times it was domesticated by the Carthaginians, and was the species generally imported by the Romans, but no succeeding African race has had the sagacity to make use of it. It is killed in vast numbers for the sake of its ivory, of which an enormous quantity is annually brought to Europe; and in so wasteful a fashion is this slaughter carried on, that the species will probably soon be exterminated. Although so well known to the ancients, it is only quite recently that live African elephants have been brought to Europe in modern times. There was one in Antwerp in 1863, and two years later a pair were obtained by the Zoological Society, which are still alive and well, the male having attained a height of ten feet. Since this, numbers of these animals have been imported down the Nile from the Soudan, and they are now common in menageries.

In size there is not much difference between the two species, and the maximum height would appear to be about eleven feet; an Indian elephant shot by Sir Victor Brooke reached that stature, which was not exceeded by the tallest of eleven hundred individuals measured by Dr. Falconer. In external appearance the two species are easily distinguishable. The African elephant has a lighter and more shapely head, a less protuberant forehead, and a larger eye, but its most striking peculiarity is the enormous size of its ears. It also stands proportionately higher on its legs, and has a more arched back. The number of nails is different, being four on the fore feet and three on the hind, whereas in the Indian species these feet have four and five nails respectively. Sportsmen say that the height of an elephant always equals double the circumference of the foot, and this is confirmed by the individuals now in the Gardens; in the male the proportion is absolutely correct, and in the female it is within three inches. The mental characters of the Indian and African elephants are different, the latter being bolder, quicker, and more obstinate.

In considering the general structure of the Elephants, the first peculiarity to be noticed is the trunk, which is really an enormous prolongation of the nose and upper lip. It is almost entirely composed of a complex mass of muscles which give it its great power and flexibility, and it is amply supplied with nerves. The great massiveness of the head is not owing to the size of the brain, but to huge air-cells in the body of the bones, which are an extraordinary development of the frontal sinuses. This expansion is necessary to afford room for the attachment of the great muscles which wield the head and proboscis.

The teeth of the Elephant are very peculiar. The tusks, which answer to the middle incisors of man, sometimes reach a weight of 150 lbs., or even, it is said, of 200 lbs. each. They have no enamel, being entirely composed of *ivory*—a peculiarly fine, tough, and elastic dentine—and are persistent in growth throughout life. Thus, if bullets happen to lodge in the pulp-cavity they are carried down by the growth into the tusk itself, in which they are sometimes found embedded. The molars are six in number in each side of each jaw, and are composed of alternated transverse plates of enamel, dentine, and cement. Owing to the different hardness of these materials they wear unequally, and produce cross ridges on the surface of the tooth, which form it into an admirable grindstone for crushing the food. The molars are not deciduous, but move forward in a curious way; only one (or at most a part of two) is in use at once, and each as it is worn away is pushed forwards by its successor, which eventually takes its place. The six teeth last out the life of the animal, which is said to extend to a hundred years or more. In the Asiatic species the plates of the molars are much finer and more regularly parallel than in the African elephant, in which they are fewer in number and have somewhat of a lozenge shape.

It was formerly a widespread delusion that the Elephant had no joints, and even now many people believe that their joints move in the contrary way from those of other quadrupeds. The explanation of this lies in the fact that the elbow and knee of an elephant are much nearer the ground than those of a horse or a cow, and are thus confused by a casual observer with the so-called "knee" (the true wrist) and "hock" (the true ankle) of the latter animals.

Although the Elephants are now so isolated among animals, it was not always so. They have many fossil relatives whose range once extended all over Europe (including Britain), Asia, North America, and part of South America. Of these the most generally known is the Mammoth, of which specimens have been so wonderfully preserved in the Siberian ice, and which was closely allied to the living Asiatic species. Going further back we have the Mastodon, in which the grinding teeth were much less differentiated and more like those of other animals. Beyond this it is difficult to trace their relationships. Possibly they may have been through the Dinotherium, or through some of the wonderful creatures whose remains have recently been discovered in the Eocene formations of America. But it is clear that in the Elephants we have the last remaining representatives of a mighty and once numerous race which have played their part in nature and disappeared, and it is only too probable that the survivors also are doomed to speedy extinction.

* Continued from p. 93.

SCIENCE IN GERMANY

(*From a German Correspondent.*)

IT is not only due to the quantitative increase of scientific work, but also to the exigencies of the division of labour, that the German serials dedicated to zoological and anatomical research have been augmented by two new ones this year.

The *Morphologisches Jahrbuch*, edited by Carl Gegenbaur, Professor at Heidelberg, unites anatomy and the history of the development of animals in their mutual and intimate relation as animal morphology. It has for its first object the recognition of the intimate relations amongst different degrees of animal organisation, and further, to consider the anatomy of man as illustrated by the knowledge of the construction of lower organisms. This programme evidently excludes all descriptions and one-sided observations which cannot be used for the above purpose. The first number contains papers on the extreme ends of the animal world, viz., Man and Infusoria, and thus illustrates the end in view most perfectly. The *Jahrbuch* will be supplemented annually by a yearly report of the progress of the anatomy of Vertebrata. This serial appears quarterly in numbers of from 6 to 10 sheets of text, with plates, at the price of from 6 to 9 marks.

Zeitschrift für Anatomie und Entwickelungsgeschichte ("Journal of Anatomy and History of Development"), edited by W. His and W. Braune, Professors of Anatomy at the University of Leipzig. The principal object of this new serial is to be the knowledge of the human body; but papers will also be received which touch upon this theme from a somewhat more distant point of view. At the same time attention will also be turned to the practical side of this subject as well as the theoretical, and materials will be offered to the medical man which will be of immediate use to him in his sphere of action. The double number published of this serial shows that its programme has very wide limits and will eventually be of interest to the zoologist and anatomist, as well as to the practical physician. A number of this serial will be published every two months, containing about five sheets of text and five plates, at the price of from 6 to 8 marks.

NOTES

THE Local Secretaries of the Bristol Meeting of the British Association are doing all in their power to make it in every way a success, and to secure the comfort and enjoyment of those members who may attend; and we think we may promise all who do a pleasant time of it. Although the railway companies have obdurately refused to grant any special concessions to those who will attend the Bristol Meeting, we have reason to believe that the usual complaints as to hotel charges will not have to be made; all the principal hotels have given assurance that their tariffs will not be raised, except in the case of beds, the charge for which, quite naturally, will be slightly increased. There are many places of scientific as well as general interest in and around Bristol; and the Bristol Museum, one of the best provincial collections in the kingdom, will be temporarily enlarged for the occasion. Excursions to various places will be arranged, and the Mayor and inhabitants of Bath have signified their wish to receive a visit from the Association. At the *soirée* on August 26 the Bristol Microscopical Society, assisted by the Naturalists' Society and the Bath Microscopical Society, has undertaken to give a systematic microscopic demonstration of the natural history of the neighbourhood; a novel feature will be the number of living objects which will be exhibited. At the second *soirée*, Aug. 31, a number of objects of great scientific interest will be exhibited. A special Guide Book is being compiled, and a very useful map of the country for many miles round Bristol has been prepared.

THE section of the Eclipse Expedition which went to Camorta returned last week. No detailed news has been received from the Siam party.

AT its last private sitting, the Paris Academy of Sciences was apprised by its Administrative Commission that the expense for the several Transit of Venus expeditions had exceeded by 80,000 francs the sum granted by the Government. A supplementary credit will be asked for from the Versailles Assembly; and M. Leverrier proposed to offer to the Government the instruments used by the several expeditions, which now belong to the Academy. These 6-inch and 8-inch refractors are large enough to be utilised in the establishment of local observatories in several provincial towns of France and Algiers. The motion was unanimously accepted on condition that the said instruments should be lent to the Academy for the Transit expeditions of 1882.

THE number of Prof. Huxley's students in Edinburgh University now amounts to upwards of 350.

THE gentlemen whose names we mentioned in a previous number (vol. xi. p. 497), were, at the annual election meeting of the Royal Society last Thursday, elected Fellows.

THE Norwegian Government has granted a credit of 4,000*l.* for an expedition to be sent out next yearunder the scientific direction of Dr. Mohn, for the exploration of the sea between Iceland, the Faroe Islands, Spitzbergen, and Jan Mayen. The commander of this expedition will be Capt. Carr Wile, of the Royal Norwegian Navy, who is now in England gathering information as to the work done by the *Challenger*.

WE take the following from the *Academy*:—Under the title of the Belgian Society of Dredging and Marine Exploration, a society has been formed for the systematic exploration of the North Sea. The annual subscription is to be 15 francs. The materials as collected are to be submitted to various scientific men who have made the different departments their special study, and are afterwards to go to form a central collection accessible to all the members. Duplicate specimens not required for this purpose are to be sold each year at one of the meetings of the Society. The circular which has been issued suggests that, by means of such a society, Belgium may be able to contribute its share to the advancement of that branch of science for which so much has been done by our own countrymen. We need not say that we wish it every success.

WE are glad to learn that Capt. Hoffmeyer, director of the Royal Danish Meteorological Institute at Copenhagen, intends to continue the publication of his daily Synoptic Meteorological Charts for the third quarter, June to August 1874. The charts are constructed from every available source for the region embraced, viz., from about lat. 30° to 70° N., and from long. 40° W. to 40° E. of Paris. The cost of subscription in this country is 12*s.* 6*d.* for the three months, but as only a limited number is printed, application should be made at once to Mr. R. H. Scott, director of the Meteorological Office, 116, Victoria Street, London, S.W.

WE understand that Prof. Boyd Dawkins, of Owens College, leaves this week for Sydney, *viâ* the Suez Canal. After conducting a geological exploration in Australia, he intends returning by San Francisco, reaching England in October, thus making the circuit of the world in about 120 days.

AT its last sitting the Council of the Paris Observatory passed resolutions relating to the observation of intra-Mercurial planets and the determination of the velocity of light by the satellites

of Jupiter and by aberration. These last researches are intended for the verification of the numbers obtained by the parallax of the sun and by Cornu's direct experiments. A beginning will be made as soon as the necessary funds have been granted by the Ministry. The intra-Mercurial planets are to be observed photographically when crossing the disc of the sun. These researches will be commenced as soon as the fitting up for photographic purposes of the great Arago refracting telescope is finished.

IT is expected that the French Academy of Sciences will hold its annual meeting for distribution of prizes on the 21st inst.

M. LABOULAYE, a Professor in the College of France and an influential member of the French Assembly, read, at the sitting of the latter on June 5, a report, drawn up by him in the name of a special commission, asking the establishment in France of Free Universities. M. Wallon, the French Minister of Public Instruction, is said to be greatly in favour of the scheme.

A STRANGE case of poisoning is reported from Stettin. A gentleman had bought a hat in a shop there, and, after having worn it for one or two days, was troubled with unbearable headache; at the same time little ulcers formed upon his forehead, his eyes were inflamed, and the whole of the upper part of his head was much swollen. It was evident that these symptoms were caused by the hat, and upon examination by a chemist it was found that the brown leather in the inside of the hat was coloured with a poisonous aniline dye. It appears that inflammation is unavoidable when this dye is in contact with any part of the skin.

DR. OSCAR FRAAS, director of the Natural History Museum and Professor of Geology at Stuttgart, has arrived at Beyrût, invited by Rustem Pasha; he intends to study the Lebanon geologically and mineralogically, and to work out a geological map of that range of mountains.

THE great meeting of German ornithologists took place at Brunswick on May 20–23. Brehm, Cabanis, Homeyer, Blasius, Reichenow, Pralle, and many other members of the two ornithological societies, were present. The first meeting led to the union of the two societies. It was resolved to request all the members to report to a Committee from time to time all observations of interest to science, agriculture, or the economy of forests, that they may make, on the life, manners, use, &c., of German birds. The Committee is to publish the materials thus obtained, after due consideration and sifting.

IN a letter dated Constantinople, May 20, the *Kölnische Zeitung* gives some details on the earthquake which took place on the west coast of Asia Minor. On the 11th of May, at 5 A.M., a severe shock was felt at Smyrna which lasted several seconds. Two other shocks followed the same morning, and although many houses were shaken, yet none fell. It is thought that the centre of the earthquake was in the Sporades Islands. According to other reports on the dreadful earthquake of the 3rd–5th of May in the interior, the sources of the Mæander river were indicated as the centre of the volcanic action. This point is situated in the canton of Ishikli, to the south of Ushak and Afium Karahissar. The destruction was fearful at Ishikli: about 1,000 houses were completely destroyed and several thousand people killed; only about twenty dwelling-houses and two mosques are now standing. In the village of Yivril not one of 300 houses is left, and about 450 dead have been extricated from the ruins. Not far from there an immense chasm has formed in the ground, from which is running a stream of hot water. The village of Yaka is likewise annihilated. In other villages, as Savasli, Karayapli, &c., the inhabitants escaped with a violent shock.

A REUTER'S telegram, dated New York, June 7, states that an earthquake has occurred at the Loyalty Islands, a tidal wave at the same time sweeping over three villages.

AT a meeting of the Upper-Rhenish Geological Society, which took place at Donaueschingen on May 23, Dr. Knop, of the Polytechnic Institution of Karlsruhe, read an interesting paper on the phenomenon of disappearance of the waters of the Danube, in some rugged piece of ground over which the river flows near Immendingen. Dr. Knop has been ordered by the Baden Government to investigate the matter scientifically. It is supposed that the little river Aach, which flows into the Lake of Constance, and thus into the Rhine, is the result of this phenomenon, as there can be no doubt that the volume of the Danube is considerably diminished after having passed over the spot in question. The present, *i.e.* the visible source of the Aach, is near the village of the same name, and the river flows from a cavern of several hundred feet in circumference, from underneath overhanging rocks, with great velocity and force; it turns several waterwheels close to its source. A chemical analysis of its water is now being made, with a view of ascertaining whether the water is of the same composition, *i.e.* contains the same impurities as that of the Danube.

SEVERAL writers in the *Belgique Horticole* have given the results of their experience in managing marine aquariums. A certain Mr. Bauwens says that he has possessed a marine aquarium now nearly ten years, *and the sea-water has never been renewed.* All that he does is to add fresh water as the salt water evaporates, the same degree of saltness being invariably maintained. Various species of small seaweeds and several molluscs thrive without further care, but some species of Actinia raised in the same medium were starved to death when the owner was absent from home for a considerable time. He made it a practice to feed them with a little mould, worms, or even raw meat.

THE quality of water in relation to its fauna and flora has been the subject of investigation by some of the French Academicians. In substance the results seem to prove that water in which animals and plants of higher organisation will thrive is fit to drink; and, on the other hand, water in which only the infusoria and lower cryptogams will grow is unhealthy. If the water become stagnant and impure, aquatic plants of the higher order will languish and disappear, and the half-suffocated fish will rise near the surface and crowd together in parts where there may still be a little of the purer element trickling in, and if driven from these places they soon die. *Physa fontinalis* will only live in very pure water; *Valvata piscinalis* in clear water; *Limnæa ovata* and *stagnalis* and *Planorbis marginatus* in ordinary water; and, finally, *Cyclas cornea* and *Bithynia impura* in water of middling quality—but no mollusc will live in corrupt water. Plants also exercise a reactive influence on the quality of water. The most delicate appears to be the common watercress, the presence of which indicates excellent quality. Veronicas and the floating water-weeds flourish only in water of good quality. The water-plantain, mints, loosestrife, sedges, rushes, water-lilies, and many others, grow perfectly well in water of moderately good quality. Some of the sedges and the arrow-heads will thrive in water of very poor quality. The most hardy or least exacting in this respect is the common reed, or *Phragmites communis.*

AMONGST the recent additions to the Southport Aquarium are a Sturgeon, seven-and-a-half feet in length, captured at low tide in the estuary of the Ribble, and a large specimen of the Wolf Fish (*Anarrhichas lupus*), from Norway.

THE foundation-stone of an aquarium was laid at Rothesay, in the Island of Bute, on Saturday.

TO-DAY, at the Mansion House, a public meeting will be held in connection with the Cambridge University Extension Scheme; the Lord Mayor will preside.

In last week's *Journal* of the Society of Arts will be found a very interesting paper by Mr. P. F. Nursey, C.E., on Toughened Glass.

The Conversazione of the Society of Arts will be held on the 25th inst. at South Kensington Museum.

Mr. Watts, who visited Iceland last year, and ascended the Vatna Jökel to a higher point than had previously been reached by any traveller, sailed from Granton last week for Reykjavik. He is to resume his travels in the interior of Iceland during the present summer. There is still a large portion of the island unexplored, and, as it is very mountainous and covered in some places with perpetual snow, the work of exploration is attended with great danger and difficulty. With the assistance of some of the Icelanders, however, it is hoped that this inhospitable region may be crossed over and examined, so that its topographical and mineralogical character may be determined more exactly than has yet been done.

A letter from the Secretary of the Italian Society of Sciences to the Paris Academy, states that the Italian *savants* have agreed to support a proposition issued by the Royal Society of Edinburgh, that the large tables of logarithms calculated by M. Prouy should be published at the common expense of all nations wishing to contribute to an enterprise of common interest for mankind. These tables were calculated as far back as the beginning of the present century, at the expense of the French Government. The manuscript, which escaped the vandalism of the Communists, is safe in the Archives of the Academy, and cannot be published solely for want of funds.

Dr. Nachtigall, the African explorer, has received the commands of the German Emperor to wait upon his Majesty at Ems. The Berlin Geographical Society gave Dr. Nachtigall an enthusiastic reception on the 2nd inst., at which the eminent traveller briefly sketched his six years' work in North Africa. The reception was followed by a banquet in the Zoological Gardens, at which Dr. Nachtigall received an autograph letter from the Emperor conferring upon him the Order of the Royal Crown. On Tuesday last the traveller was received in audience by the Imperial Crown Prince at the new Palace at Potsdam.

Preparations are being made for the erection of a handsome new museum in Dunedin, New Zealand.

The boys and girls who assembled in the theatre of London University on Monday for the distribution of prizes and certificates gained in the Cambridge University local examinations were particularly fortunate in having as chairman Sir W. V. Harcourt. The address he gave was unusually pointed and impressive; the criticism he made on the results of these examinations, and the wholesome truths he uttered on what education really means, must have had an excellent effect on many of those who heard them, both old and young. "The object of education," the chairman reminded his hearers, "was not the immediate knowledge which it gave them, but it was the instrument by which they might learn hereafter." When parents and teachers are universally impressed with this great truth, we may expect to see something like a revolution take place in our educational systems. These local examinations have one excellent result in bringing out the directions in which particular classes of pupils are apt to fail, and ought to be of great service to teachers who aim at making a science of their profession.

Owens College, Manchester, has received the first instalment, 57,000 dols., of a legacy left to it by Mr. Charles Clifton, an American engineer, a native of Yorkshire. A considerable additional balance is expected to be handed over presently.

The *Pandora*, three-masted schooner, originally a despatch vessel belonging to the Government, and which was purchased a few months ago from the Admiralty for private Arctic exploration, is now lying in the inner dock at Southampton, after having undergone a thorough overhaul and refit. The *Pandora* has been specially adapted for an Arctic cruise. She will leave England about the 18th inst., and, as Lady Franklin is understood to be largely interested in her equipment, the *Pandora* will probably follow in the footsteps of M'Clintock in search of further remains of Sir John Franklin. The vessel is propelled by a feathering screw, is of 439 tons burden, and a quick sailer. The *Pandora* will be commanded by Mr. Allen Young, who has already seen much Arctic service, and Lieut. Lillingston, R.N.

Just before the leaving of the Arctic Expedition a deputation from the Bremen North Pole Society visited Portsmouth with a view to consulting Capt. Nares regarding co-operation between the English Expedition and a German Expedition which may possibly be sent out next year.

The first Annual Report of the Yorkshire College of Science at Leeds is as satisfactory as could be expected. The College was opened in the end of last October with three professors—A. W. Rücker, Mathematics and Physics; Dr. T. E. Thorpe, Chemistry; and A. H. Green, Geology and Mining. Though the number of day-students has been small, the professors report in satisfactory terms of the progress that has been made. In addition to the day lectures, short courses of evening lectures have been given, which have been most successful. At the request of the Wakefield branch of the Ladies' Council of the Yorkshire Board of Education, arrangements were made for the delivery at Wakefield of a course of lectures, by Prof. Green, on the Geology of the West Riding; the lectures were in every way a success, and this field of operations is likely to be developed. The Clothworkers' Company had endowed a Chair of Textile Industries; the professor, Mr. W. Walker, commenced his lectures to a good class, but for some reason resigned his chair in January. On the whole, this Report is an encouraging one, and if the friends of the scheme only persevere and see that the College is founded on a sufficiently broad basis, we have no doubt of its ultimate complete success.

The following statistics have been published by the French Minister for Public Instruction:—Thirty per cent. of the population cannot read or write, but the proportion is smaller amongst the males, as the conscription lists give only nineteen per cent. at nineteen years of age. There are thirteen scholars for every 100 inhabitants, and one school for every 500, or 70,000 schools for the whole of France. The expenses of primary education are 70,000,000 fr.—about 40*l.* per school, or about 1*s.* 8*d.* per head of inhabitants, or 12*s.* per pupil.

We regret to learn from the *Geographical Magazine* that through the omission of the French Commissioners to ask the German Government to appoint a Commissioner to the forthcoming Geographical Exhibition at Paris, it is not likely to be very complete so far as maps are concerned. The absence of the great German map-publishing firms would be matter for regret.

The additions to the Zoological Society's Gardens during the past week include a Brown Capuchin (*Cebus fatuellus*) from Guiana, presented by Mr. Charles Wilson; a Kuhl's Deer (*Cervus Kuhlii*) from the Bavian Islands, two Victoria Crowned Pigeons (*Goura Victoriæ*) from the Island of Jobie, two Bornean Fireback Pheasants (*Euplocamus nobilis*) from Borneo, two Great Black Cockatoos (*Microglossa aterrima*) from New Guinea, a Derbian Screamer (*Chauna derbiana*) from S. America, purchased; a Chimpanzee (*Troglodytes niger*) from W. Africa, six Argus Pheasants (*Argus giganteus*) from Malacca, deposited; four Peacock Pheasants (*Polyplectron chinquis*), an Eland (*Oreas canna*), and a Virginian Deer (*Cervus virginianus*) born in the Gardens.

SCIENTIFIC SERIALS

Poggendorff's Annalen der Physik und Chemie, Nos. 3 and 4, 1875.—These parts contain the following papers:—Remarks on electro-dynamics, by F. Zoellner. These refer to Ampère's law and Helmholtz's potential law.—On the proportion of temporary magnetism to the magnetising force and its relation to the reciprocal action of the metallic particles, by E. Boernstein.—Remarks on the paper of Dr. Streintz, on the torsion oscillations of wires, by O. E. Meyer.—On the conducting resistance at the points where metallic conductors touch, by F. C. G. Müller.—On the specific heats of the elements carbon, boron, and silicon, by Dr. H. F. Weber; this is the first paper on the subject, and treats on the dependence on temperature of the specific heats of the isolated elements in question.—On the path of the rays of light in a spectroscope, by Dr. J. L. Hoorweg.—On electrodes which cannot be polarised, by A. Oberbeck.—On the conduction of electricity in electrolytes, by W. Beetz.—Supplement to K. L. Bauer's paper (vol. 153, p. 572, of these *Annals*) on the apparent position of a point of light situated in a denser medium, by the author.—General theorems on the images of spheric mirrors and lenses, by the same.—On the theory of the process of assimilation in the vegetable kingdom, by E. von Benkovich.—On a simple method of finding the poles of a rod magnet, by F. C. G. Müller.—On the determination of the velocity of light and the parallax of the sun, by A. Cornu. This paper is taken from the *Comptes Rendus*.—On the unipolar conduction of electricity through layers of gases of different conducting capacity, by C. Braun.—New researches on the currents in electric machines, by F. Rosette.—Some remarks on Helmholtz's theory of vowels, by E. van Qvanten.—On the theory of anomalous dispersion, by H. Helmholtz.—On an electric fall machine, by H. Waldner.—On the experimental determination of diamagnetism by its action of induction, by A. Toepler.—On an optical method of studying the oscillation of solids, by O. N. Rood.—On a new kind of variation sounds, by V. Dvorak.—On the spectrum of the zodiacal light, by Arthur W. Wright (from the *American Journal of Science*).—Some remarks on Thomson's electrometer, by K. A. Holmgren.—Electroscopic note by the editor.

Geographical Magazine, May.—A long and interesting article on the late Admiral Sherard Osborn is the first and chief article in this number, and is followed by one on the Arctic Expedition. Other articles are on "The Salt-farms of the Loire," by Horace St. John; an interesting account of the town of Kulja, in Russian Turkestan, by A. Vámbéry; on the Khivan Mission to India in 1871, by Robert Michell; a short article on Dr. Nachtigall's travels in Africa, with a well-constructed map; besides reviews, reports of societies, &c.

Zeitschrift der Oesterreichischen Gesellschaft für Meteorologie, April 1.—In continuation of his article in the last number, Dr. Hann proceeds to calculate from the formula (I.) the gradients of two storms, one of which was violent at Vienna on January 27, 1874, and the other a tropical hurricane which passed over the island of St. Thomas on August 21, 1871. In the first case ΔB, expressed in millimetres per 50 miles, amounts to 3·125, of which 2·7 is due to the rotation of the earth, and ·4 to centrifugal force. In the second, the earth's rotation causes a difference of 1·25, and centrifugal force of 8·87, the whole ΔB being 10·12. A difference of pressure amounting to 9·02 at a distance from the centre of 57 miles, is caused in this case by a velocity of 30 metres per second. Thus, in storms of small diameter, the effect of centrifugal force greatly exceeds, and in our cyclones falls far short of, that of the rotation of the earth. If the air streams towards or (in lofty regions) from the centre, another factor must be introduced into equation (I.) representing resistance to movement. Now, in spiral gyration, the full centrifugal force is not exerted, and we may divide the real velocity into two components, one in the direction of the tangent, and the other at right angles to it. Calling the angle between the direction of movement and the tangent i, the first component will be represented by $v \cos i$, and on this depends the centrifugal force. Finally, we have, according to Ferrel, for a spiral storm the equation—

$$\text{(II.)} \quad \Delta B = \frac{l}{287 \cdot 4} \cdot \frac{B}{T} \cdot \frac{(2n \sin \phi + u)v}{\cos i}$$

where $u = \dfrac{v \cos i}{r}$ where r = distance from axis of rotation. Dr. Hann remarks that that portion of the gradient derived from $2n \sin \phi v$ is really independent of the value of i, but according to the formula it increases with the increase of i, and this must be an error. Besides, the second factor, representing centrifugal force, on analysis appears to be independent of i, and so we get too large a quantity for the gradient. With respect to the velocity of the wind, we see that the rate cannot be proportional to ΔB alone in all parts of the cyclone in the same latitude; and further, that in different latitudes the value of v for the same gradient is nearly inversely proportional to the sine of the latitude. On the subject of tornadoes, Dr. Hann says that if the earth were not rotating, the tendency of the air to restore equilibrium would prevent any greater disturbances than those which are now observed at the equator. Water before at perfect rest, when an orifice is made in the containing vessel, flows through without producing circulation, but the least original movement causes rapid rotation. In tornados the influence of the rotation of the earth is small in comparison with that of the original condition of the atmosphere. Hence the variable direction of rotation. Large cyclones are not found near the equator. Tornadoes, having no constant force acting to maintain them, must soon be spent. The direction of progression of cyclones can be explained by the inequality of centrifugal force on their north and south sides. On the north side, that part of the gradient depending on $2n \sin \phi$ is greater than on the south side; the cyclone accordingly moves in the direction of least pressure, viz., towards higher latitudes.

Der Zoologishe Garten.—In the number for March, J. von Fischer remarks on the habits in captivity of the common and Mozambique Ichneumons (*Herpestes ichneumon* and *H. ornatus*); the former is more diurnal and arborial in its manner of life, and is much more playful and tameable than the latter.—A. Petry gives an account of a viper (*Pelias berus*) which gave birth in solitary confinement to one young one, and *fifteen weeks* later to three more.—E. Buck remarks on the life of various species of *Acineta* in the aquarium, and Herr Director Rueff on the history of zoological gardens.—A curious instance of the attachment of the cuckoo (*Cuculus canorus*) to its egg is recorded on the authority of Herr Förster Amort by Victor Ritter von Tschusi-Smidhofen, and Herr von Bothmer gives an interesting account of two tame otters (*Lutra vulgaris*).

Jahrbuch der Kais-Kön. geologischen Reichs-Anstalt. No. 3, band xxiv., 1874. *Hierzu*: Dr. G. Tschermak, *Mineralogische Mittheilungen*, band iv., heft 3.—The first paper in this number of the *Jahrbuch* is one by Ludw. v. Vukotinovic, on the tertiary strata in the neighbourhood of Agram (Croatia). These are divided into two groups, the *lower*, consisting of limestone (nullipore in part), with which is associated sandstone, sometimes fine-grained, sometimes coarse, and pale grey sandy marls; the *upper* (brackish group) being composed of grey and yellowish brown sandstone, yellow or white sand, and gravel and shingle. In general, a striking resemblance can be traced between these Agram tertiary deposits and the strata of the so-called Vienna basin. This holds good with at least the Upper Tertiary or Miocene; but as regards the brackish water group, some difference obtains. But this the author believes is only what might have been expected when consideration is had to the varying local conditions under which the deposits must have been accumulated. An account of the brown coal of Croatia and Slavonia is furnished by C. M. Paul. He tells us that brown coal occurs at five different geological horizons in the Tertiary strata of those districts. According to the index, we should have a paper by Dr. O. Lenz, on the ancient glacier of the Rhine, but it does not appear in this number.—Among the *Mineralogische Mittheilungen* we note specially two papers: Petrographical observations on the west coast of Spitzbergen, by Dr. R. v. Drasche; and on some trachytes of the Tokay-Eperieser Mountains, by Dr. C. Dölter. The rocks this author describes are augite andesite (augite andesite lava), amphibole-andesite, quartziferous augite andesite, rhyolite (quartziferous sanidine trachyte), and sanidine trachyte lava; analyses of a number of these rocks are given. There is also an interesting preliminary notice of a new circular-polarising substance, by Dr. C. Hintze.

Allgemeine Schweizerische Gesellschaft für die gesammten Naturwissenschaften.—The publication of this society, vol. xxvi (1874), contains only one, but a very elaborate treatise, with two plates, on the ants of Switzerland. It gives their classification, their habits, anotomical and physiological notes regarding them, and remarks on their geographical distribution, together with many new observations regarding their mode of life, &c. The author is Dr. Auguste Torel. The treatise occupies no less than 480 quarto pages, and is written in French.

SOCIETIES AND ACADEMIES

LONDON

Chemical Society, June 3.—Prof. Abel, F.R.S., &c., in the chair.—The following papers were read :—On the effects of pressure and cold upon the gaseous products of the distillation of carbonaceous shales, by Mr. J. T. Coleman. He finds that 1,000 cubic feet of the gas produced in such large quantities at shale oil works when submitted to pressure will give about one gallon of volatile hydrocarbons fit for improving the illuminating power of ordinary coal-gas.—On the agricultural chemistry of the tea plantations of India, by Dr. C. Brown, giving analyses of the ashes of tea and the effect of fertilisers on the growth of the plant.—On the structure and composition of certain pseudomorphic crystals having the form of orthoclase, by Mr. J. A. Phillips.—Note on the sulphates of narceine and other narceine derivatives, and On the action of organic acids and their anhydrides on the natural alkaloids, Part V., both by Mr. G. H. Beckett and Dr. C. R. A. Wright.—On the action of chlorine on pyrogallol, by Dr. J. Stenhouse and Mr. C. E. Groves; with an appendix by Mr. Lewis, on the crystalline forms of *mairogallol*, one of the products.—On nitro-alizarin, by Mr. W. H. Perkin, F.R.S. This compound, obtained by the action of nitric acid on acetyl-alizarin, dyes fabrics mordanted with alumina of an orange colour, whilst the amido-alizarin obtained from it by reduction gives a fine purple.—On some metallic derivatives of coumarin, by Mr. R. Williamson.—On the action of dilute mineral acids on bleaching powder, by F. Kopfer.

Geological Society, May 26.—Mr. John Evans, V.P.R.S., president, in the chair.—The following communications were read :—On some peculiarities in the microscopic structure of felspars, by Mr. Frank Rutley. The observations recorded in this paper related mainly to some exceptional features in the striation of felspars from various localities, involving a consideration of the extent to which dependence may be placed on the discrimination of monoclinic and triclinic felspars by the methods usually recognised in ordinary microscopic research. Some other peculiar structural features were likewise noticed, and the effects which might be produced on polarised light by the overlap of twin lamellæ in thin sections of felspars, when cut obliquely to the planes of twinning, were also considered. The paper terminated with a list of conclusions deduced from the observations recorded. These conclusions mostly related to matters of detail; but the general inference drawn by the author was that the present method of discriminating between monoclinic and triclinic felspars by ordinary microscopic examination answers sufficiently well for general purposes, although it is often inadequate for the determination of doubtful examples, and that such examples are of more frequent occurrence than one would at first be led to suspect.—On the Lias about Radstock, by Mr. Ralph Tate, A.L.S. In this paper the author described several sections in the Lias of the neighbourhood of Radstock, in Somersetshire, with special reference to their palæontological contents and to the question of the division of the Lias into zones in accordance with the species of Ammonites occurring in different parts of the series. He maintained that although the Lower Lias in this district only attains a thickness of twenty-four feet, this is due to poverty of sediment; and that whilst by this means the zones are compressed, and the species of Ammonites brought almost into juxtaposition, the succession of Ammonite-life is as regular in the Radstock Lias as in the most typical districts. Much of the opposition to the doctrine of zoological zones he ascribed to erroneous discrimination of species. The paper included tables of sections and lists of fossils, with the arguments founded upon them, in support of the above opinion. A few new species were described under the names of *Trochus solitarius*, *Cryptæna affinis*, *Cardita consimilis*, and *Cardinia rugulosa*.—On the axis of a Dinosaur from the Wealden of Brook, in the Isle of Wight; probably referable to *Iguanodon*, by Prof. H. G. Seeley, F.L.S. This perfect specimen, preserved in the Woodwardian Museum of the University of Cambridge, is 3½ inches long and 3¼ inches high. The odontoid process is anchylosed to the axis, and projects forward as in the axis of birds, so as to articulate with the occipital condyle of the skull. The pre- and postzygapophyses are situated much as in birds; as are the two ovate pedicles, on the anterior part of the side of the vertebra to which the cervical rib was articulated. But posteriorly the articular surface for the third cervical vertebra is transversely ovate and slightly concave. The neural spine is compressed from side to side, more so in front than behind. Among mammals, the nearest resemblance to this kind of axis is seen similarly in the whale; and among reptiles the crocodile has a two-headed rib; but the other characters are more like those of *Hatteria*, which the author regarded as a near ally of the Crocodilia and Chelonia, and as wrongly united with the Lacertilia.—On an Ornithosaurian from the Purbeck Limestone of Langton, near Swanage (*Doratorhynchus validus*), by Prof. H. G. Seeley, F.L.S. The author obtained these specimens (a lower jaw and a vertebra) in 1868, and described them in the "Index to the Secondary Reptilia, &c., in the Woodwardian Museum in 1869 as *Pterodactylus macrurus*. He now believed that the Ornithosaurian vertebræ from the Cambridge Greensand, which have been regarded as caudal, are really cervical, and therefore that the analogy on which this vertebra was determined to be caudal cannot be sustained; he proposed to adopt for his species Prof. Owen's specific name *validus*, given in 1870 to a phalange of the wing finger from the same deposit. The vertebra is five inches long, relatively less expanded at the ends than similar vertebræ from the Cambridge Greensand, has strong zygapophysial processes and a minute pneumatic foramen. The lower jaw, as preserved, is 12¼ inches long. The symphysis extends for five inches, and is about one-eighth of an inch deep, and divided into two parts by a deep median groove. The teeth extended for eight inches along the jaw, and about seven or eight occurred in the space of an inch. They were directed outward in front, and became vertical behind. Where the rami are fractured behind they measure 2¼ inches from side to side.

Zoological Society, June 1.—Dr. Günther, F.R.S., V.P., in the chair.—Mr. Sclater made some remarks on the most noticeable of the animals seen by him during a recent visit to the Zoological Gardens of Rotterdam, the Hague, Amsterdam, Antwerp, and Ghent.—Mr. Sclater exhibited the typical specimen of his *Centropsar mirus* (P.Z.S. 1874, p. 175, Pl. xxvi.), and stated that on a more careful examination of it he had come to the conclusion that it was a made-up skin.—Mr. Edwin Ward exhibited the two lower canine teeth of a Hippopotamus from St. Lucia Bay, S. Africa, obtained by the Hon. C. Ellis, and supposed to be the largest ever obtained. They measured from end to end round the outer curve thirty inches.—Mr. G. E. Dobson read a paper on the genus of Insectivorous Bats named *Chalinolobus*, by Dr. Peters, and gave the descriptions of several new or little known species of this group, which he proposed to divide into two sections, *Chalinolobus* and *Glauconycteris*.—A communication was read from Mr. Henry Adams, wherein he gave the descriptions of two new land shells. These were proposed to be named respectively *Eurycratera farafanga*, found on a sandy plain in the S.W. of Madagascar, near the Farafanga River, and *Pupinopsis angasi*, from the Louisiade Archipelago, in the S.E. of New Guinea.—Mr. G. French Angas communicated the descriptions of three new species of shells from Australia, proposed to be called *Helix forrestiana*, *H. broughami*, and *Euryta brazieri*.—Mr. A. G. Butler read a paper describing several new species of Indian Heterocerous Lepidoptera.—A communication was read from Rev. O. Pickard-Cambridge on some new species of spiders of the genus *Erigone* from North America.—Mr. Herbert Druce communicated a list of the collection of Diurnal Lepidoptera made by Mr. J. J. Monteiro in Angola, with descriptions of some new species.—Mr. P. L. Sclater read a paper on several rare or little known mammals now or lately living in the Society's collection, amongst which was specially noticed an apparently new species of Muntjac, proposed to be called *Cervulus micrurus*.—A communication was read from Mr. E. L. Layard, containing notes on the birds observed by him in the Fiji Islands.—Lieut.-Col. R. H. Beddome read a paper in which he gave the descriptions of some new operculated land shells from Southern India and Ceylon. The discoveries of true *Diplomatina* in Southern India and of *Nicida* in Ceylon were alluded to as being of special interest.—Sir Victor Brooke, Bart., read some supplementary notes on African Buffaloes, in the course of which he stated that he had come to the conclusion that the West African Buffalo (*Bos pumilus*) was distinct from the East African form (*Bos æquinoctialis*).—Mr. C. G. Danford exhibited specimens of the Wild Goat (*Capro aegagrus*, Gm.), from Asia Minor, and read some notes on the distribution, habits, &c., of that species.

Royal Microscopical Society, June 2.—Mr. Charles Brooke, F.R.S., vice-president, in the chair.—Mr. J. W. Stephenson exhibited and explained a simple method which he had devised for enabling any person to measure the angle of aperture of an objective, and a number of copies of the engraved

scale employed for the purpose were placed upon the table for distribution amongst the Fellows.—Mr. Charles Stewart gave an interesting account of the results of an examination into the minute structure of *Bucephalus polymorphus*, and illustrated his observations by drawings.—Mr. Slack then at some length explained the use and management of Mr. Wenham's reflex illuminator, and pointed out the means of obviating the difficulties which were found to arise when it was used in connection with objectives of large angles.

Victoria (Philosophical) Institute, June 7.—The President in the chair. This was the ninth annual meeting, and the report showed that since last year the number of subscribing members had increased by 116, and now reached 601, two-thirds of whom were country and foreign members. Papers had been read during the session by Professors H. A. Nicholson, T. R. Birks, J. Challis, and others; and the outside demand for the publications had doubled each succeeding year since 1871. The report having been adopted, the annual address was then delivered by the Rev. Robert Main, Radcliffe Observer. The address was of three sections:—1. A sketch of most important discoveries in physics, chiefly astronomical, which have been made during the last few years. 2. A slight review of some of the assumptions in two recent publications, namely, Mill's "Essay on Theism," and Strauss's "Old and New Faith." 3. A consideration of the Atomic Philosophy in connection with Dr. Tyndall's Belfast address.

BERLIN

German Chemical Society, May 24.—W. Petrieff described the products of the decomposition by heat of dibromomalonic acid, namely an oil, C_2HBr_3, and dibromacetic acid.—W. Wisth and A. Landolt have transformed bromaniline into parabromobenzoic acid, by converting it into the corresponding mustard oil $C_6H_4Br - N = C = S$, and transforming this into the nitrale $C_6H_4Br - C \equiv N$.—A. Weber has studied mononitrodimethylaniline and monobromodimethylaniline.—M. Nencky has transformed indol into nitrosoindol-nitrate

$$C_{16}H_{13}(NO)N_2 . NO_3H,$$

which sulphide ammonium converts into hydrazindol

$$(C_{16}H_{13}N - NH)_2$$

—H. Limpricht retracts his opinion of the existence of four isomeric monobromobenzenesulphonic acids, the fourth being identical with that obtained from sulphanilic acid.—F. Fittica, however, still insists upon the existence of four mononitrobenzoic acids, but makes it more improbable than ever by stating that the fourth isomeride is transformed by tin and hydrochloric acid into the body $C_{12}H_{12}N_2O$!—H. Hassenpflug has been able to convert nitrobenzene into paranitrobenzoic acid, by treating it with peroxide of manganese and sulphuric acid.—L. Klippert has studied the action of fluoride of silicium on ethylate of sodium. It results in the formation of sodium fluoride, silicium fluoride, and silicic ether.

VIENNA

Imperial Academy of Sciences, Jan. 7.—Prof. K. Puschl presented a memoir on the changes in the volume of caoutchouc by heat. The author gives as the results of his experiments, (1) that the density of caoutchouc reaches a minimum at a certain temperature; (2) that the temperature of this minimum changes according to the mechanical tension, and is the lower the greater the tension; (3) that with caoutchouc upon which no tension is applied, the temperature of the minimum of density is higher than the ordinary temperature; (4) that the reverse of this is the case with caoutchouc under strong tension.—Director von Littrow then made some communications regarding Borrelly's comet.—Prof. E. Suess presented a paper on the volcano Venda, near Padua.—Prof. Dr. Winckler then read a treatise on the integration of two linear differential equations.—Dr. Doelter gave a preliminary account of the geological nature of the Pontinic islands.—Dr. von Littrow communicated a paper on the relative capacity of different soils for conducting heat and the corresponding influence of water.—Dr. Lippmann presented a memoir on the action of iodine upon mercuric oxide. The author shows that whenever a hot solution of iodine acts upon mercuric oxide, an iodate always is formed besides the mercuric iodide, and that it is indifferent whether the solution be made in alcohol, benzine, chloride of carbon, butylic alcohol, acetone, or water.—Prof. Schlesinger then presented a memoir on a metallic barometer without mercury.

PARIS

Academy of Sciences, May 31.—M. Frémy in the chair.—The following papers were read:—Researches on sulphides, by M. A. Cahours.—A note by M. L. Saltel, on left curves.—On the alterations in the level of the Seine in the environs of Paris, from November 1874 to May 1875, by M. A. Gérardin.—On a new method of preparing highly concentrated formic acid, by means of anhydrous oxalic acid and a polyatomic alcohol, by M. Lorin.—A note by M. J. Riban, on the isomerism of the chlorohydrates $C_{10}H_{16}$. HCl.—Researches by M. E. Faivre, on the functions of the front ganglion of *Dytiscus marginalis*.—On the organisation and the natural classification of the Acarina of the Gamasea family, by M. Megnin.—Experimental researches on the toxical properties of putrefied blood, by M. V. Feltz.—On chronical aortite, by M. P. Jousset.—On a new method of treating rheumatism of the brain by chloral hydrate, by M. E. Bouchut.—On the improbability of an interior sea or lake having existed formerly on the Sahara desert, by M. Pomel.—On the influence of drought upon Cryptogamæ, by M. E. Robert.—On the origin of Phylloxera at Cognac, by M. Mouillefert.—A note by MM. Ph. Zoeller and A. Grete, on the use of xanthate of potash against Phylloxera.—A note by M. Julien, on the presence of Phylloxera in the Auvergne.—A letter from M. Villedieu, on the influence of moisture upon Phylloxera.—A letter from M. Reymonet, on the possibility of grafting vines on little trees the roots of which cannot serve as food for Phylloxera.—A letter from M. F. Moll, on the use of a mixture of soft soap and dead oil (as used for railway sleepers) against the larvæ of cockchafers and snails.—A number of communications of minor interest were then read; most of them were competition papers for the various prizes the Academy distributes annually.—Researches on the rate of magnetisation and demagnetisation of wrought-iron, steel and cast-iron, by M. M. Deprez.—A note by MM. V. de Luynes and A. Girard, on the rotatory power of crystallised sugar and on the polarimetric analysis of various sugars.—Researches on the emissive power of leaves, by M. Maquenne.—Remarks by M. A. Bechamp, concerning a note by M. Gayon, read at the meeting of April 19 last, on the spontaneous alterations in eggs.—A note by M. A. Gautier, on the production of blood fibrine.—A note by M. Grimaud de Caux, on a case of psoïtis.

BOOKS AND PAMPHLETS RECEIVED

CROLL'S "CLIMATE AND TIME"

Climate and Time in their Geological Relations; a theory of Secular Changes of the Earth's Climate. By James Croll, of H.M. Geological Survey of Scotland. (London: Daldy, Isbister, and Co., 1875.)

MR. CROLL is well known as an original thinker of considerable power, who has turned his attention to the physics of geology, and has produced a series of remarkable papers on questions of the highest interest in that subject. His views are opposed in many respects to those accepted by other influential thinkers, and have given rise to a considerable amount of controversy. Hitherto they have been scattered in papers to various periodicals, and it has been difficult to obtain a consecutive view of them. The work which is now issued, while not an actual reprint of previous papers, is a complete exposition of their contents, or at least of that part of their contents that Mr. Croll is prepared to stand by, some of the arguments that occur in his papers being omitted in his book. We are now therefore able to judge fairly what truth there is in Mr. Croll's ideas, and to compare them with those of his opponents. Even were all his ideas untenable, we should still have to thank him for his vigorous discussion of these interesting questions, but there can be no doubt that in many instances he proves his point.

Mr. Croll does not possess the happy faculty which some authors have of carrying his readers with him: on the contrary, his style is so controversial, that to agree with him is to have the feeling of being vanquished, and the reader is throughout set on his metal to find out some flaw in the argument. This, as in most cases of controversy, it would not be difficult to do; but we must confine ourselves to the discussion of his main results.

One peculiarity of Mr. Croll's arguments must here be noticed. After having assumed certain figures and arrived by their means at definite results, he proceeds to show that these figures are unreliable, and then to state that their unreliableness will not affect his results; or else, in order to bring his results more into accordance with received opinions and probable facts, he generously halves them or diminishes them still more, apparently unaware that had his arguments been correct and his first results the true ones, he would have proved too much and refuted himself. Examples of this peculiarity will be seen in the sequel.

The first question discussed is the heating influence of the Gulf Stream. To estimate this Mr. Croll uses the method of heat units, and prides himself on doing so. The method is an undeniable one, and is perhaps the only one by which the influence of the high specific heat of water can be made manifest. Mr. Croll compares the number of foot-pounds conveyed by the Gulf Stream into temperate regions with the number due to the heat of the sun shining directly on those regions. The relative value of these depends on the absolute value of each. The volume, velocity, and temperature of the Gulf Stream have been very variously estimated; and as to the sun's heat, when we remember how much the diathermancy of the air depends on its condition, we may not be able to accept with such confidence as Mr. Croll, the estimates of Pouillet; yet with every possible allowance, when the influence of a vast body of heated water is calculated, it will undoubtedly be much greater than would have been previously supposed, and actually amounts to a very considerable fraction, say $\frac{1}{16}$ of the whole of the sun's direct heat on the North Atlantic. Dr. Carpenter * brings objections against this method which render, in his opinion, the "figures" "utterly valueless." The first of these is that Mr. Croll does not give a correct account of the difference in temperature between the northern and southern hemispheres in assigning it to the transport of heated water by ocean currents; but it is obvious that the question as to where the Gulf Stream obtains its heat is entirely distinct from that as to its actual amount. The second objection, that since the temperature of the ocean is seldom more than 82°—86°, while the "direct heat of radiation" may amount to 215°; and therefore that "the heat lost by evaporation from the sea must be far greater than that lost by radiation from the land," is just one that shows the *value* of Mr. Croll's method. For, when treated in this way, the above figures show that the sea contains *more heat units* in its heated surface stratum than the layer of land that is influenced by the variations of surface-temperature, and that therefore the water at the equator is, as Mr. Croll states, the best adapted for retaining the heat of the sun, which is in reality no more than an elementary result of its high specific heat. Mr. Croll considers that the influence of the Gulf Stream is indirect, being manifested by the warming of the S.W. winds; and to the extent that he proves that the Gulf Stream raises the general temperature of the Atlantic he cannot be wrong. Were he to confine himself to the statement that the Gulf Stream and other ocean currents have a very sensible influence on the climate of the temperate regions, his position would appear to be impregnable against any who should represent its thermal effect "as very insignificant;" but when he adds that "ocean currents are the great agents employed" (to the exclusion of others) "in the distribution of heat over the globe," and estimates that the Gulf Stream alone raises the mean temperature of London 40°, he stands upon less certain ground. For these results depend on the following arguments:—(1) There is no ocean circulation but that by sensible currents; (2) The internal heat of the earth has no influence on climate; (3) The temperature of space is − 239° F.; and (4), the Gulf Stream supplies $\frac{1}{5}$ as much heat to the Atlantic as the direct rays of the sun. Of these arguments we will below discuss the first at length. The second is founded on a statement of Sir Wm. Thomson's, that an increase of temperature as great as 2° F. per foot in descending into the earth would not have an influence of more than 1° on the climate of the surface. This, however, means 1° over the present mean temperature, and in no way disproves that the internal heat of the earth does nothing in raising the temperature of its surface over that of space, an effect which it most certainly would have in a large degree. The third argument, as to the temperature of space, is therefore nothing to the point, and is moreover, as Mr. Croll himself admits,

* Proceedings of the Royal Society, June 13, 1872.

totally unreliable. We do not know the temperature *from* which the sun raises the earth, except that it is greater than that of space. The fourth argument, of course, is nothing without the first three, and the fraction $\frac{1}{5}$ we have seen may be much too large. We are not, then, in a position to estimate accurately the thermal effect of the Gulf Stream and other ocean currents; but we may consider it proved, as is indeed generally acknowledged, that they have a very sensible influence, and, as we shall see, bear a great part in the general circulation of the ocean water.

We must now examine how far Mr. Croll establishes his position that a general oceanic circulation is impossible under the influence of temperature and gravitation alone. Dr. Carpenter has already given (Proc. of Roy. Geog. Soc., vol. xviii.) his reasons for his belief in the adequacy of these influences, and his replies to Mr. Croll's objections, some of which are discussed in this volume in no less than four chapters. Although it may be familiar to most of our readers, it will be well to give here an outline of Dr. Carpenter's "doctrine."

The chilling of the salt water in both polar regions renders it heavier and causes it to sink, its place being supplied from the warmer water of lower latitudes, which is itself supplied by the motion of the water from the two poles towards the equator along the lower portion of the ocean; and these two masses meeting each other near the equator, well up there, and bring the colder water nearer the surface, while the heating of the surface water in these regions keeps up the difference between the specific gravities of the water supplied to and leaving the polar regions, on which the whole depends. These appear to be Dr. Carpenter's latest views (Proc. Roy. Geog. Soc., vol. xviii., June 1874), though Mr. Croll's objections seem, in some part at least, to be aimed at details that do not affect the fundamental conception. This is distinguished as a *vertical* circulation, because the first origination of the motion is supposed to be in the *descent* of the polar waters. Mr. Croll assents to the facts, but ascribes the circulation to the initiation of the winds, and denies that there is any circulation beyond that produced by currents. We know that currents exist on the surface, and it is generally agreed that they owe their origin, in great part at least, to the system of prevailing winds, and even on Dr. Carpenter's theory they must, so far as they tend polewards, decrease by so much the general circulation of the upper ocean; but the known or assumed under-currents are much more local, and the depression of temperature at great depths is too general to allow us to conceive that the return should be made by circumscribed currents.

In discussing the question whether the polar cold is sufficient to cause circulation, Mr. Croll first objects that the sea of the tropics is salter, and therefore denser, than that of the poles, and that this would counteract the effect of the cold. There is in reality but little force in this objection as against Dr. Carpenter's theory. The excess of temperature and of salinity counteract each other in the surface layers of the tropics, and prevent them sinking or rising; but as they have a nearly horizontal motion, according to the theory, the objection is nothing, the lower layers which alone have an upward vertical motion deriving it from a *vis-à-tergo*; and with regard to the polar area the lower layers cannot be more salt than the upper, from whence they come, according to the theory, and any *freezing* on the surface must leave the remaining water on the contrary salter.

The next objection of Mr. Croll is far more formidable, though it shows that some of the *proofs* adduced are untenable, rather than the theory itself. The drifting of icebergs from Newfoundland across the Gulf Stream, and of the Atlantic cable buoy which travelled six hundred nautical miles in seventy-six days, adduced by Dr. Carpenter as proving the southward motion of the deeper layers, proves too much according to Mr. Croll, as it proves the existence of a sensible *current*, which Dr. Carpenter admits cannot be formed by differences of gravity. This may be true, and prove that other causes operate in the motion of large masses of water; but while destroying one argument in favour of, it proves nothing in opposition to, the doctrine of general oceanic circulation. This class of objections, however, are far more forcible than theoretical ones; and the list of phenomena that may be accounted for on either theory, and of those that cannot well be accounted for on the gravitation theory, *e.g.* the southward currents of Davis Straits and the east coast of Greenland, shows that neither theory *alone* will satisfy all the conditions to be fulfilled. Mr. Croll, however, gives no satisfactory account of the greater cold of the lower strata of the South Atlantic, nor of the surging up of cold currents on eastern shores, nor of the cold water coming nearest the surface under the equator; nor does his theory give that beautiful account of the maintenance of life in the deep sea which is so dependent on the change of the water.

But Mr. Croll asserts that the gravitation theory is physically faulty, and maintains the assertion in this volume against Dr. Carpenter's last reply. In several of his arguments it is impossible not to agree with him. In examining them we will follow the order he takes. He first shows that heat at the surface, as in the equatorial regions, cannot produce circulation. But this, though essential to Lieut. Maury's theory, has not been asserted by Dr. Carpenter, who, on the contrary, states that any effect due to the heating at the equator may be practically disregarded; and why? because the heat is here applied at the top instead of at the bottom, as it should be to produce convection; but an application of cold to the top would be equivalent to heat at the bottom, and this cold is obtained in the polar area; consequently Dr. Carpenter regards polar cold as the *primum mobile*. Mr. Croll objects to this that it is the *difference* of temperature only we have to do with, and this may be said to depend on either, and accuses Dr. Carpenter with confusion of ideas; but this is scarcely fair after arguing against the heat being available to produce motion because applied at the top, showing that he perceived that not the difference *only*, but *where* the lower temperature is found is of consequence. Dr. Carpenter would say the temperature at the poles is *below* the average, no matter how that average is obtained; which is a very different thing from saying the equatorial temperature is *above* the average—since in the first case the average might be obtained, as far as the theory is concerned, by a nearly *uniform* temperature elsewhere.

The next important question raised with respect to this theory is the amount of force which is exerted to put the

water in motion. This Mr. Croll shows to depend entirely and only on the amount of slope of the water-surface from the equator to the pole, and not at all upon the amount of fall from the surface in the polar regions, to the lowest depth at which the water of maximum density s found beneath the equator. Dr. Carpenter says that this "would seem irreconcilable with the simplest principles of physics," a statement easier to make than to prove. For, as Mr. Croll shows plainly, the work done *by* gravity in the descent, is done *against* gravity in the ascent at the equator, and the two counteract each other, except only the extra amount of gravity which is called into action by the shrinkage of the polar column from what would have been its size under the *average* amount of solar heat, and which alone can have any *continuous* effect. The solar heat is a constantly supplied moving force which is used indirectly in the ocean circulation, and any further amount of gravity made use of in the circuit would involve the idea of perpetual motion. Connected with this is Dr. Carpenter's assertion that there is *no* difference of level between the equatorial and polar seas. Since, however, this is the *only* proximate cause for the ocean circulation, its denial would seem to cut the ground from beneath his feet. It will be found, however, that though he denies it in one place he asserts it in another, and his theory essentially depends on it. It is true that water *tends* to find its level when disturbed, as it is by the action of polar cold, which tends to alter its level; but it is just this *tendency* that causes the circulation. If one of the forces were to be powerful enough to have its own way entirely, no motion could occur; *i.e.* if the water were too viscous, a greater permanent change of level would arise; if it were *perfectly* fluid, the equilibrium would be brought about *instantaneously* and no visible motion would be perceived. We must be content, then, with the fall of level from equator to pole to produce the circulation: is it sufficient? This depends entirely on the viscosity of water. Mr. Croll bases his argument on the experiments of Dubuat, who showed that water would not descend a slope of 1 in 1,000,000, which is much greater than the slope under discussion, and hence the fall of level is too small to cause any circulation. He replies to Dr. Carpenter's objection, that these experiments had reference to water running over solids and not over itself, by saying that one layer of molecules alone would be in contact with the solid and the rest with the water surface only. The reply is plainly beside the mark, as Mr. Croll should have seen by reading Dr. Carpenter's statement following his objection, that the difference between a fluid restoring its own equilibrium, and having a sensible motion over solid surfaces, was well known in practice to Mr. Hawksley and other hydraulic engineers. But in reality no chamber experiments can determine such a point satisfactorily; and besides this, it seems to us that an important point has been overlooked by Mr. Croll. No doubt it would be hard for a single pound of water to perform its whole circuit against all opposing frictions under the impulse of the force due to so small an amount of slope; but if large masses of water move together, the moving force would be proportional to the mass, but the friction to be overcome would be simply that of the perimeter of the tube of flow, and it is an essential part of the theory of ocean circulation that the moving water is of immense mass. This friction would not increase, like statical friction, with the mass, since the pressure would be the same at the same depths, and it is also more of the nature of shearing force than friction, and therefore nearly a constant quantity.

It does not appear, then, that anything that has been said by Mr. Croll disproves this theory of a general oceanic circulation, though he may have successfully attacked it in certain respects. Nevertheless we agree with him that "if a vertical motion follows as a necessary consequence from a transference of water from the equator to the poles by gravity, it follows equally as a necessary consequence from the same transference by the winds; so that one is not at liberty to advocate a vertical circulation in the one case and to deny it in the other."

This was the opinion also of Herschel in his letter to Dr. Carpenter, that "henceforward the question of ocean currents will have to be considered under a twofold point of view." It would take too long to discuss the other points in which Mr. Croll enters into controversy with respect to various currents, such as the Gibraltar or the Baltic, and we must reserve for another notice the interesting points connected with past time with which the latter part of the book is occupied. J. F. B.

(*To be continued.*)

HILDEBRANDSSON ON UPPER ATMOSPHERIC CURRENTS

Essai sur les Courants supérieurs de l'Atmosphère, dans leur Relation aux Lignes Isobarométriques. Par H. Hildebrand Hildebrandsson. (Upsal, 1875.)

CLEMENT LEY, in "The Laws of the Winds prevailing in Western Europe," expresses his opinion, based on observations made near Hereford on the movements of the cirrus cloud, that in general the upper currents of the atmosphere flow away from the regions of low atmospheric pressure, and converge upon regions ot high pressure. This being a point of the utmost importance with reference to the general circulation of the atmosphere, M. Hildebrandsson, in December 1873, organised a systematic observation of the cirrus cloud in Sweden. Twenty of the Swedish meteorological observers engaged in the work of observation, the network of stations extending over nearly 11° of latitude, from Tomarp in the south to Qvickjock in the north. The above essay discusses these observations with great ability.

The question of the relation of the motions of the cirrus cloud to areas of high and low pressure is cleverly handled in the essay, and the method of discussion, illustrated by thirty-three charts, may be referred to as a satisfactory and exhaustive treatment of the data of cirrus observation, which are restricted only to one country. Charts I. to VIII. represent well-selected instances of storms advancing on Sweden from westward; Charts IX. to XVI. represent Sweden in the rear of storms; and Charts XVII. to XXIV. represent areas of high pressure in various directions, S., E., &c., from Sweden. Comparing the direction of the upper currents with these areas of high and low pressure, it is shown that quite near the centre of the depression area of storms the upper currents blow in directions nearly parallel to the isobars and to the winds on the surface of the earth, but that in

proportion as we proceed from the centre they are turned outwards, being deflected to the right of the surface winds; in other words, they tend more and more to blow out from the area of low pressure. On the other hand, they converge upon the centre of the regions of high pressure, cutting the isobars nearly at right angles. This last point is interesting in connection with the circumstance pointed out some time ago by Hoffmeyer, that surface winds in blowing out of the areas of high pressure cut the isobars approximately at right angles. Charts XXV. to XXXII. are selected to represent instances in which Sweden lies between two storms, the one following the other with only a short interval between them. In these cases the behaviour of the upper currents from both storms and the manner in which they blend together at their contiguous margins are very instructive.

The winds on the surface of the earth, as compared with the upper currents, show, as is well known, inverse relations to areas of low and high pressure—blowing inwards upon areas of low pressure, and outwards from areas of high pressure. Consequently, as the author remarks, an area of low barometer is necessarily the region of an ascending current, which, when it has risen to a great height in the atmosphere, flows away from the central space of low pressure towards regions of high pressure, whence it sinks gradually down to the surface as a descending current, and in this manner a vertical circulation is constantly maintained between the surface of the earth and the higher limits of the atmosphere. We very strongly recommend that, as has been so successfully carried out in Sweden, a thorough and systematic observation of the cirrus cloud be generally inaugurated in other countries, so that it may be possible to chart the upper currents over a wide extent. Among the many points suggested by M. Hildebrandsson's charts is the question whether the extent and volume of the upper currents flowing outwards from storm areas be consistent with some of the views recently advanced on the theory of storms and circulation of the atmosphere. We hope meteorologists will soon take steps to occupy the important field of observation now opened up.

OUR BOOK SHELF

The Zoological Record for 1873. Edited by E. C. Rye, F.Z.S. (London: J. Van Voorst, 1875.)

In the preface to the "Record" for 1872 Prof. Newton, the editor, announced that having intimated to the Zoological Record Association his intention to resign his post, the Council had appointed Mr. Rye, Librarian to the Royal Geographical Society, as his successor. From a glance into the present volume it is evident that it is Mr. Rye's intention to maintain the high standard of his predecessors, notwithstanding the difficulties he has had to encounter, especially in the loss of the services of Dr. Günther, whose increased duties, now that he has been promoted to the post of Keeper of the Natural History Department of the British Museum, prevent him from undertaking the *Mammalia*, *Reptilia*, and *Pisces*, as he has done for years. Mr. Rye has succeeded in obtaining the services of Mr. E. R. Alston, F.Z.S, on the Mammals, and of Mr. A. W. E. O'Shaughnessy on the Reptiles and Fishes; both which naturalists have most creditably performed their laborious tasks. Mr. R. B. Sharpe has undertaken the Birds as before, whilst Dr. Ed. von Martens, the Rev. O. Pickard-Cambridge, Mr. Rye, Mr. Kirby, Mr. McLachlan, and Dr. Lütken, have devoted themselves to their special subjects. The editor acknowledges the grant of 100*l.* from the British Association, 50*l.* from the Zoological Society, and 100*l.* from the Government Grant Committee of the Royal Society (this being the first occasion that the Record Association has been so assisted), towards the expenses of publication. The increasing necessity for the production of the volume is yearly becoming more evident, at the same time that its contents are necessarily of such a nature that there can never be a demand for it which will enable it nearly to cover its expenses. The most important scientific results of the year include the investigations of Leidy, Marsh, and Cope on the fossil American Eocene Mammalia, and Prof. Marsh's discovery of a new sub-class of fossil toothed birds, respecting which all naturalists cannot but regret that so little opportunity is given them of seeing specimens or even drawings of the great number of species now known to them by short descriptions only.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Systems of Consanguinity

I am sorry to find that on some points I have misunderstood the views of my friend Mr. Morgan (vol. xii. p. 86), and the more so as, after reading his letter very carefully, I am not sure that I quite comprehend them even now. Your reviewer is no doubt able to reply for himself: but it certainly seems to me not remarkable that both he and I should have been led into error. Indeed, I do not exactly understand whether Mr. Morgan intends to say that we have misapprehended his views in supposing that in his opinion one of the two great systems of classification of relationships is "arbitrary, artificial, and intentional." Mr. Morgan admits that he himself used these terms in several places. There are, he says, "three or four places, and perhaps more, in that volume in which I speak of the system of a particular people as 'artificial and complicated,' and as 'arbitrary and artificial,' without the qualification in each case which should, perhaps, have been inserted." Thus your reviewer and I were, as he himself allows, using his very own words, though I shall of course omit them if my book should reach a fourth edition.

Moreover, these descriptive epithets are not used casually, but form the very basis of his argument. For instance, in p. 469 he says:—

"It may be remarked, however, that if the system is to be regarded as exclusively natural and spontaneous, the argument for unity of origin would be without force; since, as such, it would be the form to which all nations must insensibly gravitate under the exercise of ordinary intelligence. But if to reach the descriptive system these families have struggled out of a previous system, altogether different, through a series of customs and institutions which existed antecedently to the attainment of the state of marriage between single pairs, then it becomes a result or ultimate consequence of customs and institutions of man's invention, rather than a system taught by nature." *

But then, as I understand, he alleges that a different theory is given in his concluding chapter. So far, however, from finding in that chapter any indication of a change of opinions, I see that he reiterates the same view. After discussing the classificatory system, he says: "There would seem to be but four conceivable ways of accounting for the joint possession of this system of relationship by the Turanian and Ganowánian families; and they are the following:—First, by borrowing from each other; secondly, by accidental invention in disconnected areas; thirdly, by spontaneous growth in like disconnected areas, under the influence of suggestions springing from similar wants in similar conditions of society; and fourthly, by transmission with the blood from a common original source." †

After negativing the two first hypotheses, he proceeds to discuss the third, namely, that of "spontaneous growth under the influence of suggestions springing from similar wants in similar

* Morgan's "Systems of Consanguinity and Affinity of the Human Family," p. 469.

† Ibid. p. 500.

conditions of society." This possible theory, he says, "has been made a subject of not less careful study and reflection than the system itself." But after a patient analysis and comparison of its several forms, he comes to the conclusion that it is insufficient to account for the facts.

Thus, as it seems to me, he clearly repudiates the theory of spontaneous growth.

Mr. Morgan thinks that his solution of the problem of relationships must have escaped my notice, because I did not discuss it in my paper read before the Anthropological Institute; but in that memoir I quoted from the chapter in question, and went on to say—

"Mr. Morgan admits that systems of relationships have undergone a gradual development, following that of the social condition; but he also attributes to them great value in the determination of ethnological affinities. I am not sure that I exactly understand his views as to the precise bearing of these two conclusions in relation to one another; and I have elsewhere given my reasons for dissenting from his interpretation of the facts in reference to social relations."

Thus I expressly pointed out that Mr. Morgan, while characterising the "classificatory" system, to use his own terms, as "arbitrary and artificial," nevertheless also regards it as having "undergone a gradual development following that of the social condition." Surely Mr. Morgan must have written his letter without having my book by him, for it seems to me that the above passages, taken together, represent his own theory, as given in his letter. Mr. Morgan hints that the conclusions contained in his last chapter had escaped my notice. He appears to have overlooked the fact that I quoted from that very chapter. I was not, however, reviewing his work, and differing fundamentally, as I do, from the conclusions adopted by him, while feeling deeply also the great obligations to him under which ethnologists lie, I preferred to state my own views rather than to dwell on the differences between the conclusions at which he and I have arrived. JOHN LUBBOCK

Down, Kent, June 7

Attraction and Repulsion caused by Radiation

I DID not intend to reply to Prof. Osborne Reynolds' letter in NATURE, vol. xii. p. 6, but some persons expect me to say something about it. If the Professor would be careful not to answer me with the ideas that occur to him as he is "on the point of sending off the paper" (see Phil. Mag., Nov. 1874), he would save himself the trouble of many explanations. After my thousand experiments it is scarcely respectful to try to overcome all by his few, and, after three years of my thought, rather hasty to tell me that he explained it all so suddenly with perfect certainty, and that I am unable to comprehend him. It is also scarcely wise to lead us to infer that probably he cannot explain the whole, but that he knows somebody who will soon do it.

Prof. Reynolds seems to base his calculations on some of my experiments which dealt with a perceptible amount of gas, and has not taken notice of those where there is no amount of gas known to be present; for example, in a chemical vacuum.

Prof. Reynolds must show that there is gas or vapour remaining, and he must also show that there is enough to produce the mechanical results. He tells us that the forces will increase as the density of the gases diminishes. The speed will, but if the force does, that can only be up to a certain point, when it is equally certain that a change will take place, and the motion of the particles or molecules will be attended with less force according as they diminish in number. The opposite to this involves something not intended. I suppose he does not intend to speak of forces without matter. The analogy with sound is not quite happy, as that is so readily diminished by lower pressure; although the speed is the same, the power is small. Besides this, what will he say to the case where there is no heat and only light? I am abundantly willing to allow molecules and forces, but I see no place for such as I have been acquainted with.

I am working at the subject and shall be glad to come to a true conclusion. Scientific men need not be so very much afraid of a new law of nature, for some are wanted, and there are certainly many yet waiting to be discovered before nature becomes intelligible to us.

I by no means deny that the phenomena are connected with molecular movements, but I believe that Prof. Reynolds has neither explained this nor proved it by experiment. His explanation suits only a part of my work; and so does the saying that the "experiments stand in much the same relation to the kinetic theory of gases that Foucault's pendulum occupied with regard to the rotation of the earth." This is an analogy showing much acuteness, viewing the matter from what I consider the unproved side.

Prof. Reynolds goes far when he says that my experiments are "the only direct proof that has ever been obtained of the kinetic theory of gases." It may be, but if so, physicists must have been too easily pleased with their theories.

I might say much more, but I prefer to wait. There is but little good done by short notes when such a large and important subject waits for elucidation. WILLIAM CROOKES

London

American Indian Weapons

THE Pai-ute weapon, described by Mr. Mason in your last number (p. 107), although extremely interesting and quite new to me, appears scarcely sufficiently characteristic of a war weapon to form an exception to the statement of Schoolcraft, that the clubs of the North American Indians as a rule are curved. It would be interesting if it could be ascertained how such a peculiar instrument as that described by your correspondent came to be used as a weapon of war. Its form precludes the possibility of its having been designed for such a purpose. The mode of holding it suggests the idea of its having originally been used as a pounder, the thick end having perhaps been employed for pounding grain, beating out grass for cloth, or for preparing skins. It somewhat resembles the instrument used for making bark cloth in some of the Polynesian Isles, and it corresponds to the Beatle (Battelle) still used by Irishwomen for beating flax, and occasionally, I have no doubt, as a weapon of war; but these are used with the flat side, not the end. The only weapon I know of that is used like the Pai-ute club is the New Zealander's Merai or Pattoo-Pattoo, the sharp end of which is thrust into the back of the head of the offender; and I have suggested elsewhere that this peculiar and awkward mode of using it arose from its having been originally what its form resembles, a stone axe blade (celt), used as the Australians now use it sometimes, in the hand without any handle. The sharp edge at the end of the Merai shows its original intention, in the same way that the flat end of the Pai-ute club could never have been designed as an offensive weapon, but would have been useful as a pounder; it may be, in fact, a "survival" converted to other uses. There exists, of course, no law of nature to prevent North American Indians from using straight clubs as well as curved ones, but my observation of their weapons confirms the statement of Schoolcraft, that as a rule they do not. Amongst races in a more primitive state of culture, as amongst the Australians, we find that nearly every form of club that is made straight is used also in a curved form, the curvature arising merely from the natural bend of the branch out of which it was constructed; when these natural curves were found useful, they appear to have been retained and systematised. But the North American weapons are of a more advanced and conventionalised description, and we cannot trace their origin and *growth* so clearly as amongst lower savages. The description of the Moquis boomerang by Mr. Mason is an interesting fact, which, combined with the mention of it by Bancroft amongst the Pueblo Indians of New Mexico, points to the probability of a connected area of distribution. Drawings of weapons such as those given in your journal are of the utmost value in assisting to trace the distribution of like forms. A. LANE-FOX

Guildford, June 12

Hardened Glass

PERHAPS the following short and preliminary account of some observations on the optical and mechanical properties of De la Bastie's toughened, or, as I think more correctly, hardened glass, may interest your correspondent Mr. James H. Logan (vol. xii. p. 87).

Immediately after the publication of M. De la Bastie's specification I prepared specimens of the glass, I submitted them to careful optical examination by polarised light. Perhaps the best experiments are those made by means of short cylinders and small cubes and parallelopipeds carefully "hardened." A small cube with half-inch sides thus prepared has its sides ground plane and polished. The operation of polishing may be dispensed with if a small microscopical thin cover be cemented on the ground surface with Canada balsam. The cube is then mounted between strips of blackened cork, and examined in the

usual way by means of Nicol's prisms, glass plates or other appropriate polariscope. The beautiful chromatic phenomena thus brought out at once indicate that amongst the causes which operate to produce the hardness of glass, powerful compression of the interior by the contracting exterior must be one. The phenomena are, in fact, essentially those of compressed glass, and the curves of colour, or black and yellow, seen when the glass is examined by white or monochromatic light, indicate successive curves of tension and balanced, or no-tension. In a carefully prepared glass rod of half-inch length these curves are rings traversed by a well-marked black cross. In an oval the rings assume the character of those seen in biaxial crystals. When plates are examined, the light being transmitted from back to front, they appear to act essentially as bi-refracting plates, but with crosses and bands somewhat irregularly distributed, and capable of being referred to the angles of the plates or to centres of unequal heating.

My experiments on the mechanical properties of the glass have chiefly been confined to testing its hardness and the possibility of grinding it. So far as I have gone at present I make it to be nearly twice as hard as ordinary glass, which it scratches with ease. It can be cut with a good file well moistened with turpentine, and can be ground on a stone with sand, without fracturing, if great care be taken and the glass be well prepared. One piece, which manifested when under the polariscope evidences of ill-balanced tension, the neutral line lying near one surface, submitted to transverse grooving, but disintegrated on being ground on one surface as soon as the outer surface had been ground away to near the neutral line. There appears to be an easily reached limit beyond which the surfaces must not be unequally removed, but as my friend Mr. Thos. Fairley, F.R.S.E., has been good enough to show me, there is practically no limit beyond which *both* surfaces may not be *simultaneously* removed. This result, foretold by me from polariscopical analysis, Mr. Fairley has kindly shown by dissolving the opposing surfaces away by hydrofluoric acid. The least hard portions dissolved much more readily than the thoroughly hardened, and the etched surfaces show wavy lines closely following the tension lines shown by the polariscope. There is further this remarkable feature, that the inner portion of the glass proves to be essentially common glass, which fractures in the ordinary way. Further experiments are necessary for the complete elucidation of the subject, and are in progress, but the preceding may be useful to fellow-workers on the subject.

Leeds, June 12 HENRY POCKLINGTON

The House-fly—A Query

IN one of the rooms in the Science Schools lately built here, I have noticed, in the last week or so, great numbers of the large house-fly (*Musca domestica*) lying dead on the floor. Last Tuesday I saw one fall dead, but this is the only one. This morning I counted thirty-two in a space of about three square yards. I examined one under a microscope, and found that most of the small hairs on its body were covered with a yellowish powder. Can any of your readers give me any explanation of this?

Harrow, June 8 HARROVIAN

OUR ASTRONOMICAL COLUMN

VARIABLE STARS.—Mr. J. E. Gore (Umballa, Punjâb) writes, under date May 5, that he believes 27 Canis Majoris to be a variable star. It is 4 in Harding's Atlas, but at present about $5\frac{1}{2}$ or 6, and much inferior to 28 in the same constellation, which Harding rates at 5. The change of brightness was first noticed in 1874. This star is 4·5 in the Radcliffe Catalogues, 5 in Arg. Zones, $5\frac{1}{2}$ in Lacaille, and 6·5 in Heis's Catalogue; Behrmann has 6, and the lowest estimate of magnitude is 7, in Flamsteed's Catalogue, with respect to which Baily remarks that there is no magnitude recorded in the original observation-book, and that modern observations make it $4\frac{1}{2}$. Mr. Gore states he has also "suspected some variation of light in the red star 22 Canis Majoris (between δ and ϵ); it is usually rated as of magnitude 3 or $3\frac{1}{2}$, but for some time past it has seemed rather fainter than an ordinary star of the fourth magnitude." Bradley and Piazzi have this star 3·4, Flamsteed, Brisbane, and Heis, 4, the Washington General Catalogue 5, and it is so rated once by Argelander; in Behrmann it is 4·5.

We will take this opportunity of directing the attention of our astronomical readers in the southern hemisphere to Behrmann's valuable Atlas and accompanying Catalogue, which, pending the publication of Dr. Gould's Cordoba "Uranometria," is the only real authority for recent magnitudes of the naked-eye stars of the southern heavens. It is entitled "Atlas des Südlichen Gestirnten Himmels, von Dr. Carl Behrmann" (Leipsic, 1874), and contains the stars in forty-six constellations between 20° of south declination and the south pole, and is arranged upon the plan of Argelander's well-known work. The number of stars included in the Atlas is 2,344. It was formed by Behrmann in the short space of from nine to ten months, beginning in the autumn of 1866, and on that account, as the author remarks, there may probably be some omissions and errors, but it is nevertheless a very meritorious and important work. It appears, from Dr. Gould's report to the Minister of Public Instruction of the Argentine Republic, that his "Uranometria" has undergone the intended revision, and is now completed, and that steps are being taken for its publication. It is only one of the extensive scientific undertakings which will mark the residence of this distinguished and energetic astronomer at Cordoba.

THE BINARY STAR η CORONÆ BOREALIS.—Mr. Wilson, Temple Observatory, Rugby, has published some remarks upon the tendency of recent measures of this star to shorten the period of revolution assigned by computers hitherto, and refers to Winnecke's careful discussion of the measures to 1856. Winnecke's orbit, however, is not the latest that has been calculated, that of Wijkander including measures to 1870, and the period he finds, 41·58 years, is not much different from that which Mr. Wilson considers to be required by the more recent measures. Still, these later observations point to a further diminution of the period, the exact amount of which may probably be soon determined. The following angles and distances are calculated from Wijkander's orbit, and on comparison of the former with the results of observation, it will be found that the computed value is now about 3° behind the true one.

1872·0	Angle	48°·07	Distance	0″·90
73.0	,,	51 ·98	,,	0 ·86
74.0	,,	56 ·35	,,	0 ·81
75.0	,,	61 ·32	,,	0 ·76
76.0	,,	67 ·05	,,	0 ·70

This orbit gives the angle too small by 5°·3 for Sir W. Herschel's measure in 1782, and also too small by 4°·3 for his measures in 1802, or, if these differences are expressed in the form Δ sin. d P, −0″·09 and −0″·04 respectively.

Sir W. Herschel's description of his experience with this star is found in *Philosoph. Trans.* 1804. On Sept. 9, 1781, the position was 59° 19′ *n.f.*, and on Sept. 6, 1802, by "a mean of two very accurate measures" it was 89° 40′ *n.p.* (This is now found to require correction of 180°.) Herschel further states "the distance of the two stars has not been subject to any sensible alteration. Sept. 9, 1781, a very small division might be seen with 460. Aug. 30, 1794, they were so close that with a 10-feet reflector and power of 600 a very minute division could but just be perceived. April 15, 1803, with a 10-feet reflector, a very small division was also visible, with 400, though better with 600. And May 15, 1803, I saw the separation between the two stars with the same 7-feet reflector and magnifying power of 460, with which I had seen it twenty-two years before." We have from Wijkander's orbit for comparison with this account:—

1781·69	Angle	25°·4	Position	0″·98
1794·66	,,	80 ·2	,,	0 ·60
1802·68	,,	175 ·5	,,	0 ·57
1803·37	,,	181 ·6	,,	0 ·59

Except in 1781, it will be remarked, the distances at the

dates of Herschel's observations are given sensibly the same.

PROPER MOTION OF B.A.C. 793.—Prof. C. P. Smyth has lately drawn attention to an apparent variation in the amount of proper motion of the star B.A.C. 793, shown by the Edinburgh observations between 1837 and 1868, involving a diminution in the motion in R.A. and an increase in that in N.P.D. The star is No. 31 of the list included in Argelander's *Untersuchungen über die Eigenbewegungen von* 250 *Sternen*, Bonn Observations, Vol. vii., Part I., where, from a rigorous discussion of seventy years' observations, the proper motion in R.A. is found to be + 0·1245s, and that in N.P.D., – 1″·456. The comparison of the normal place for 1855·0 with the whole course of published observations to 1865, in which every refinement of calculation is introduced and the above proper motions employed, with Bessel's precession-constants, does not afford any indication of the variability of proper motion suspected by Prof. Smyth. The last Edinburgh observations in 1866 and 1867 show a difference from Argelander's formula of only – 0·08s. in R.A., and agree exactly with the N.P.D. The Washington position, depending upon two observations towards the end of 1870, is in close agreement with Argelander in R.A., and differs – 2″·0 in N.P.D. If a position of the star depending upon a good number of observations should be obtained during the present year, the point may be definitively settled, but thus far variation of the proper motion appears to be at least questionable. Upon this subject see Bonn Observations as above, pp. 20, 54, and 109.

MINOR PLANET NO. 146.—The number of small planets is rapidly approaching *one hundred and fifty*. M. Borrelly, of the Observatory at Marseilles, announces his discovery of No. 146 on the evening of June 8. At 10 P.M. its place was in R.A. 17h. 20m. 16s., and N.P.D. 111° 20′ 15″; it is as bright as stars of the eleventh magnitude, and therefore for the present should be readily identified by means of Chacornac's Chart No. 52.

SCIENCE IN GERMANY

(*From German Correspondents.*)

HERR VON BEZOLD, of Munich, has published some interesting researches on the periodical changes in the frequency of thunderstorms during long periods of time. These researches are particularly noteworthy for the original manner in which the author has used the statistical materials on thunderstorms which he could obtain (principally within the kingdom of Bavaria). As the character of our reports will not permit us to give details with regard to the manner of treatment, we pass at once to the results which Herr von Bezold has arrived at.

First of all it was found that the frequency of thunderstorms during a long period is generally either on a continuous increase or decrease, and that these variations are periodical.

If we ask on which other meteorological phenomena these variations could possibly depend, the first thing to be considered is the temperature. It is further advisable, on account of the numerous relations that have lately been discovered to exist between sunspots and meteorological phenomena, to turn attention also in this direction. It has been found in reality, that if we represent the variations of the frequency of thunderstorms by a curve and compare the same with the curve of the frequency of sunspots, the minima of the thunderstorm curve coincide exactly with the maxima in the sunspot curve. On the other hand, the thunderstorm curve forms, to a certain extent, the mean between the sunspot curve and the curve of the deviation of the average yearly temperature for our latitudes.

We must observe here that although the path of the thunderstorm curve shows a general and unmistakeable connection with that of the sunspot curve (so that, for instance, for the period from 1775 to 1822 the maxima of the thunderstorm curve coincide almost completely with the minima of the sunspot curve), yet the details of the thunderstorm curve coincide better with the details of the curve of temperatures, so that nearly every rise or fall in the latter can be distinctly traced in the former. This connection between thunderstorms and the deviations of the yearly temperatures from the total average, shows itself still clearly, even where that between the thunderstorm and sunspot curves is less apparent.

Herr von Bezold recapitulates the results of his investigations as follows:—High temperatures, as well as a solar surface free from spots, cause a greater number of thunderstorms during a year than the reverse. Now, as the maxima in the frequency of sunspots coincide with the maxima of the intensity of aurora borealis, it follows that both groups of electrical phenomena, thunderstorms and auroræ, complement each other, as it were, so that in years with many thunderstorms auroræ will be rare, and *vice versâ*.

From this connection between sunspots and thunderstorms an immediate electric action between the earth and the sun does not necessarily follow, but it may be simply a consequence of the magnitude of insolation, which depends on the frequency of spots. These changes in the insolation are not felt simultaneously but successively in the different latitudes. The phenomena of thunderstorms, however, do not only depend on the conditions of temperature at a given locality, but also on the state of the atmosphere at far distant points, belonging to another zone; and this is most evident with thunderstorms accompanying strong currents of wind or tempests. In this manner the peculiar intermediary position which the thunderstorm curve occupies between the curves of temperature and sunspots might perhaps find its explanation eventually.

IN zoological investigations experiments are rare, and therefore the results obtained by them are all the more valuable. The latest work of this kind—"Researches on the Theory of Descent: I. On the Season-dimorphism of Butterflies," by Dr. August Weismann, Professor at Freiburg—will, however, interest not only the narrower circle of entomologists, but also the amateurs in this branch of science, as it will furnish them with a sort of guide for the pursuit of their hobbies in such a manner as to do great service to science. Weismann bases his researches on the fact, which has been known for some time, and which has been called "season-dimorphism" by Wallace, that certain butterflies, when issuing from their winter chrysalis in the spring, show a different coloration and design upon their wings than do those which appear in the following summer; so that until this fact was discovered, the two forms were thought to be two distinct species of butterflies. We will only mention one of many examples, as it refers to one of the commonest kinds of day-butterflies. *Vanessa levana* is only the winter form of *Vanessa prorsa*, which is the summer form produced by the former; the latest offspring of the latter, which survive the winter, reappear as *Vanessa levana* in the following spring. Weismann exposed the caterpillars produced by *V. levana* in May, which in the normal state should have produced the imago of *V. prorsa*, to a continuous temperature of 0° – 1° C., after they had changed to nymphæ. The result was that they yielded the winter form *V. levana*, with few exceptions. The same result was obtained with the second summer generation, which under ordinary conditions would still have appeared as *V. prorsa*. On the other hand, Weismann succeeded only very rarely in forcing the last generation in the year again to take the *Prorsa* form, by keeping the nymphæ in hothouses at 15° – 30° C., instead

of in the ordinary winter temperature. Most of the nymphæ passed the winter even in hothouses or in heated rooms, and produced *V. levana* in the spring. Similar researches were made by Weismann with another common day-butterfly species, *Pieris napi*.

Weismann thinks that the winter form of these butterflies was the original one, which existed alone and in a single annual generation in Europe, during the so-called ice period. As the summers became longer and warmer, a second and finally a third annual generation could be produced, and these were changed to the *Prorsa* form by the higher temperature. The return of the colder season then always caused a return to the original form (*Atavism*), just as it occurred in the experiments. To confirm this view, Weismann quotes the fact that in Lapland and in the upper Alps only a winter form of *P. napi* exists. As with an incomplete return to the original form intermediate forms result, the varying aspects of which prove that the change of the original form always takes place in a certain direction, Weismann thinks that the change of temperature might certainly have given the impulse for a change of form, but that the particular direction of the same lies in the constitution of the animal in question. We may certainly consider as a result of these investigations, that a change of climate, together with other causes, may have directly produced a great number of different species of butterflies.

Another fact mentioned by Weismann refers to the above, and is no less interesting. There is one of the lower Crustaceæ, *Leptodora hyalina* (Siebold's and Kölliker's *Zeitschrift für Wissenschaftliche Zoologie*, 1875), which is remarkable in many ways. This animal, according to the observations of the Norwegian Sars, shows similar phenomena, as the winter breed is differently developed from the summer breed, although the perfect forms are not so widely different as those of the butterflies.

ZOOLOGICAL NONSENSE

NOT many months since a controversy which had been raging for several weeks in the columns of the so-called "leading journal" was suddenly and completely put an end to by a well-known writer in a contemporary calmly and dispassionately pointing out that both disputants had been uttering what was absolute nonsense. "I use the word nonsense," he went on to say, "not as it is often used as a vague term of disapproval, but with a strict specific meaning, as contradistinguished from sense. All words—all articulate words—must be either sense or nonsense. They are sense if their meaning can be imagined, conceived, represented in some way or other to the mind. They are nonsense if their meaning cannot be imagined, conceived, or represented in any way to the mind. When a man says, 'I saw six men and two women walking down such a street, dressed in such a way, and heard them talking on such a subject,' anyone can understand, whether he believes it or not. The speaker is talking sense, whether truly or falsely. If he were to say he saw two crooked straight lines standing in the five corners of a square, you would say he was talking nonsense, that his words were neither true nor false, and that he might as well keep silence, or utter any other unmeaning sounds. The difference between these two examples consists solely in this, that the first assertion can, whereas the last cannot, be pictured to the mind. Each particular word by itself is as clear in the one case as in the other."

What the question then under discussion was, does not signify. Enough that it was nothing which had to do with natural science. But we are sorry to say that nonsense is still occasionally spoken or written by those who, if they do not exactly profess to be scientific, yet pretend to treat of things that clearly belong to the domain of science, and so make some approach to that character. Moreover, they are looked up to by some well-meaning though imperfectly instructed persons as authorities worthy of consideration. There was a time when there was a good deal of nonsense written by naturalists, and especially by zoologists, but we had been in hopes that the practice was entirely given up. It seems, however, that we are disappointed. Here is a melancholy instance to which our attention has lately been called :—

"I have never seen any reason to doubt, *first*, that the Vertebrata, or more properly 'Endosteata,' are the central group of the animal kingdom, the others being the Exosteates (or Articulates), the Anosteates (or Molluscs), and the Actiniates (or Radiates); *secondly*, that the Sucklers are the central group of Endosteates, the other groups being Birds, Reptiles, and Fishes; the Sucklers are connected with Birds through the Bats, with Reptiles through Pangolins and Armadillos, and with Fishes through Porpoises and Whales. The pectoral sucklers (Primates) are central, and MAN is the centre of these—not a mere unit on the circumference of the system."

There is no need to name the writer of this passage or the publication in which it appeared within the last few weeks, because our business is with the matter, not with the man, though we can hardly do otherwise than marvel at his style of easy assurance—"I have never seen any reason to doubt." We at first almost fear a platitude, then catching a glimpse of what is coming, we begin to think we are on the verge of a great discovery, or perhaps shall be brought face to face with intelligence itself. Sad is our disappointment as the sentence proceeds. The unwonted word "Endosteata" jars our bones within us, but we recover as we best can, and so far suppose it is all right; the expression of a "central group" may pass as a metaphor, and we feel a sense of relief and obligation at having the extraordinary names of the other groups translated for us; but then we thought we had somewhere been taught the Radiates had no existence. However, we hail a friendly semicolon, and find that we are arrived at the end of the author's first article of faith, which, though obscured by the metaphor, is yet intelligible. Now, then, for his "secondly." The word "Sucklers" strikes us as singular, but we discover that whatever it means forms another "central group," this time of "Endosteates"; so, to meet metaphor by metaphor, we exclaim "wheels within wheels," and it is a comfort to find that the surrounding groups are our old friends Birds, Reptiles, and Fishes; Amphibians, we suppose, being packed between the two latter. The next part of the sentence, however, is absolutely shocking: "Sucklers" connected with Birds through Bats, with Reptiles through Pangolins and Armadillos, and so on. Why, what is a zoological connection? Is it of affinity or analogy? Can the author have ever seen or examined the structure of the animals he mentions? We are taken back to the dark ages of zoology, if not to ages almost prehistoric. Needless to say that our confidence is gone. Then we have the concluding sentence with the old metaphor once more, and a new one; or is it that no metaphor is intended after all? that these concentric circles forming a system with a circumference on which man is *not* a unit —we wonder who ever said he was—exist in the author's mind? In our own we are free to say they do not. We are sure that they do not exist in nature, and we are so unimaginative that we cannot picture a representation of them to ourselves. Accordingly there is no help for it but to conclude that all this is clear, unmistakable, undeniable nonsense, as much so as the two crooked straight lines standing in the five corners of a square. These "circles," with their unit-bearing circumference, are, in the words of the writer from whom we first quoted, "the nonsensical shreds of exploded metaphysics"—relics of that silly "circular system" with its mystical numbers, its fives or its sevens—the will-o'-the-wisp of fancy that once

led men's minds astray from the path where only they could find the truth they were earnestly seeking.

Those who desire to believe nonsense at all hazards and in the face of the clearest possible proofs, and indeed like it rather the better because it is so, can of course continue in their fool's paradise. Who can doubt that they see the paragon of animals in the author of the passage we have been criticising, and that he sits at the centre—the "focal point" is the choice expression, we believe—of a select circle of admiring "pectoral sucklers" the very "hub of the universe," as our American friends might say? The Report of the last Local Examination Syndicate of one of our Universities speaks of Zoology as follows :—"The general character of the work in this subject is, perhaps, even worse than it was last year. In many cases the teaching appears to have been faulty or defective ; there was a general ignorance of the principles of zoological classification ; and a great number of candidates sent up answers so full of confusion and error as to lead to the opinion that they had only prepared for the examination by a hurried attempt to learn portions of a text-book by rote." Who can wonder at this prevalent "ignorance of the principles of classification" when a zoologist in a position to give instruction to youth and encourage their devotion to the study of nature utters absurdities such as we have just been noticing? We fear that he is not alone in his mischievous folly.

LECTURES AT THE ZOOLOGICAL GARDENS*

VII.

June 10.—*Prof. Mivart on Kangaroos.*

AFTER pointing out the external and osteological characters of the Kangaroo, the lecturer proceeded to consider the question, What is a Kangaroo? what its place in the scale of animated beings ; as also its relations to space and time? At birth the Kangaroo is strangely different from what it ultimately becomes. It is customary to speak of the human infant as exceptionally helpless at birth and after it, but it is at once capable of vigorous sucking, and very early learns to seek the nipple. The great Kangaroo, standing some six feet high, is at birth scarcely more than an inch long. Born in such a feeble and imperfect condition, the young Kangaroo is not able to suck of its own accord. The mother places it on one of the nipples and squeezes its own milk-gland by means of a muscle which covers it, in such a way that the fluid enters the mouth of the young one. In most animals, man included, the air-passage opens into the floor of the mouth behind the tongue, and *in front* of the opening of the gullet. Each particle of food as it goes towards the gullet passes over the entrance to the windpipe, but is prevented from falling in by the action of the epiglottis, which stands up in front of the opening and closes over it when food is passing. But in the young Kangaroo, the milk being introduced, not by any voluntary act of the recipient, but by the action of the mother, it is evident that some special mechanism is necessary to prevent choking. This is found in the elongation of the upper part of the windpipe, which projects up into the nasal passage, and is embraced by the soft palate in such a manner that the food passes on each side of it, whilst the air does not enter the mouth at all.

The Kangaroo browses on the herbage and bushes of more or less open country ; and, when feeding, commonly applies its front limbs to the ground. It readily, however, raises itself on its hind limbs and strong tail, as on a tripod, when any sound, sight, or smell alarms its natural timidity. Mr. Gould tells us that the natives sometimes hunt them by forming a great circle around them, gradually converging upon them and so frightening them by cries that they become an easy prey to their clubs. The Kangaroo is said to be able to clear even more than fifteen feet at one bound. It breeds freely in the Society's Gardens, many being reared to maturity. They have been also more or less acclimatised in the grounds of Glastonbury Abbey, in the parks of Lord Hill and the Duke of Marlborough, and elsewhere.

It is just upon one hundred and five years since the Kangaroo was first distinctly seen by Englishmen. At the recommendation and request of the Royal Society, Capt. (then Lieutenant) Cook set sail in 1768, in the ship *Endeavour*, on a voyage of exploration, and for the observation of the Transit of Venus of the year 1769. In the spring of the following year the ship steered from New Zealand to the eastern coast of New Holland, visiting, among other places, Botany Bay. Afterwards, when detained in Endeavour River, an animal as large as a greyhound, of a slender make, a mouse colour, and extremely swift, was seen more than once. On July 14, "Mr. Gore, who went out with his gun, had the good fortune to kill one of these animals," adding, "This animal is called by the natives *Kangaroo*." Kangaroos, however, had been seen by earlier travellers, and these may even be the animals referred to by Dampier when he tells us that on the 12th of August, 1699, "two or three of my seamen saw creatures not unlike wolves, but so lean that they looked like mere skeletons."

The whole animal population of the globe is termed the Animal Kingdom, in contrast with the world of plants, or Vegetable Kingdom. The highest sub-kingdom of this is that of the Vertebrata, of which the Mammalia form the highest class, to which class the Kangaroos belong. Of these animals there are many species arranged in some four genera ; the true Kangaroos forming a genus, *Macropus*, which is very nearly allied to three others, namely, *Dorcopsis*, with a very large first grinding tooth ; *Dendrolagus* (Tree Kangaroo), which frequents the branches of trees, and has the fore limbs but little shorter than the hind ; and *Hypsiprymnus* (Rat Kangaroo), which has the first upper grinder compressed and vertically grooved. The species all inhabit Australia and the adjacent islands. They all agree in having the second and third toes slender and united in a common fold of skin ; the hind limbs longer than the fore limbs ; no inner metatarsal bone ; all the fore toes provided with claws ; and six upper together with two lower incisors. These five characters coexist in no other animal.

The family Macropodidæ is one of six which, together with it, make up the larger Kangaroo Order, the exact relations of which necessitate a cursory view of the others being taken. The Bandicoot plainly differs from the Kangaroo in external appearance, but resembles it in having the hind limbs longer than the fore, and also in the structure of the hind feet, which are similarly modified, but to a less degree, a rudimentary inner toe being present. It is an example of the family Peramelidæ, one member of which, *Chœropus*, is very exceptional, in that the hind toes, except the fourth, are exceedingly reduced and functionless, at the same time that its anterior digits are only two in number. The Phalanger is a type of the Phalangistidæ, arboreal, nocturnal animals, in which the limbs are of nearly equal length, with the second and third hind toes united, and a large opposable thumb. Some have prehensile tails, others expansions of the skin in the flanks to act as a parachute in leaping. The Koala (*Phascolarctus*) and *Tarsipes* are aberrant members ; the former without a tail, the latter with minute and few teeth. The genus *Cuscus* is found in New Guinea and Timor. The Wombat (*Phascolomys*) forms a distinct family. It is a burrowing, nocturnal animal, the size of a badger, with a rudimentary tail, as well as peculiar feet and rodent-like teeth.

The Dasyuridæ, or family of the native cat, wolf, and

* Continued from p. 114.

devil, are so called from their predatory and fierce nature. They have large canine teeth and sharp molars. The second and third toes are no longer bound together, whilst the great toe is absent or small. Myrmecobius is a peculiar genus, remarkable for the great number of its back teeth. The Tasmanian Wolf is confined to that island, and will very probably soon become quite extinct, because of its destructiveness to the sheep of the colonies. It differs from all other members of the Kangaroo order in that cartilages represent the marsupial bones found in every other member of the order. The last family consists of the true Opossums, which differ from all above referred to in inhabiting America only, not Australia. They are called Didelphidæ; one species is aquatic in habit, and web-footed.

Such are the very varied forms composing the six families which together make up the Kangaroo order. What is its relation to those of the other Mammalia? Very noticeable in it is the very great diversity of form, dentition, and habit found in the order, some being arboreal and vegetarian, others terrestrial and carnivorous, &c.; nevertheless, these so varied marsupial forms possess in common important characters by which they differ from all other mammals. These characters, however, relate mainly to the structure of their reproductive organs, as to the great importance of which characters naturalists are agreed. The angle of the lower jaw is also peculiar. Almost every mammal which has marsupial bones has the angle of its jaw inflected, or else has no angle at all, whilst every animal which has both marsupial bones and an inflected jaw-angle, possesses also those other special characters which distinguish the marsupials from all other mammals. We have, therefore, at least two great groups, one non-marsupial, containing man, the apes, bats, cats, hoofed beasts, &c.—the Monodelphia; the other containing the marsupials only—the Didelphia. There is a third group containing only the Ornithorhynchus and Echidna, which form by themselves alone a third group, Ornithodelphia.

As to its zoological relations, we may therefore say that the Kangaroo is a peculiarly modified form of a most varied order of Mammalia (the marsupials), which differs from all ordinary beasts (and from man) by very important anatomical and physiological characters, the sign of the existence of which is the coexistence in it of marsupial bones with an inflected angle of the lower jaw. As to the geographical relations of the Kangaroo, a study of their distribution over the world shows that the Kangaroo is one of an order of animals confined to the Australian region and America, the great bulk of the order, including all the Macropodidæ, being strictly confined to the Australian region.

The lecturer concluded by explaining the geological relations of the Kangaroo and its order, pointing out that in Australia we have an instance of zoological "survival" connecting the existing creation with the triassic period.

*MAGNETO-ELECTRIC MACHINES**

II.

IN 1871 M. Jamin communicated to the French Academy of Sciences a short note by M. Gramme, on a magneto-electric machine which gave electrical currents always in the same direction by the revolution of an electro-magnetic ring between the poles of a permanent magnet. The construction of the electro-magnetic or ring armature in Gramme's machine differs in some mechanical details from that of the transversal electro-magnet of Pacinotti, and the serious mistake of applying the rubbers which carry off the current at the wrong place is avoided. We must therefore regard the Gramme machine as the first effective magneto-electric machine constructed to give continuous currents all flowing in the same direction. Before entering into the details of its construction it may be useful, even at the risk of some repetition, to describe as briefly as possible the principles on which the action of the electro-magnet or ring armature depends.

In its simplest form this armature consists of a ring of soft iron, round which is wound a single closed coil of copper wire or other metallic riband, covered with silk, except at a single point in each loop of the coil, which is left exposed in order to make contacts. In Fig. 4 such a ring is shown, placed between the poles of a permanent magnet. The parts of this ring contiguous to the poles N S of the fixed magnet will acquire respectively polarity of the opposite kind to that of the neighbouring pole, while the parts of the ring O O′, at the end of a diameter

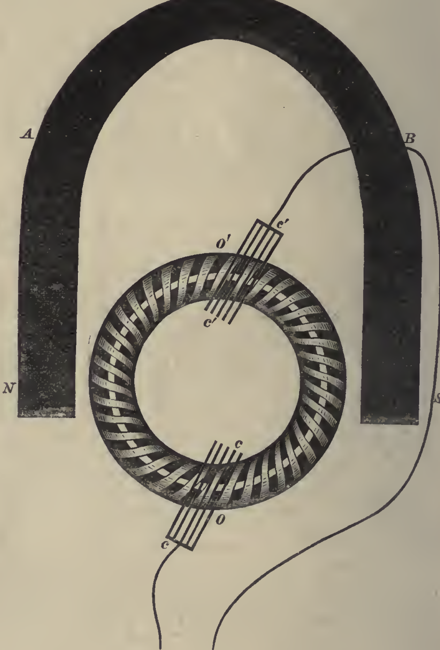

FIG. 4.—Ring Armature.

at right angles to the line joining the poles, will be neutral. If the ring is made of homogeneous metal, this statement will be strictly exact so long as it is at rest, but if it be made to revolve rapidly on an axis perpendicular to the plane of the fixed magnet, the poles of the ring, as well as the neutral points, will be slightly displaced, as M. Gaugain has shown, in the direction of the motion. This arises from what is called the coercive power of iron; that is, from the circumstance that even the purest iron will not acquire or lose magnetism in an inappreciably short period of time. The change in the distribution of the magnetism in the ring from this cause is, however, inconsiderable, and may easily be allowed for.

To make the explanation clearer, let us suppose that there is only one loop of wire, *a* (Fig. 5), upon the ring, and that this loop is moveable and in connection with a galvanometer *g*. If now the loop is moved along the ring (assumed to be at rest) from the neutral line O towards S′, a current will be developed in a certain direc-

* The substance of a Lecture, with additions, delivered at the Belfast Philosophical Society, March 17, by Dr. Andrews, F.R.S., L. & E. (Continued from p. 92.)

tion, the intensity of which will increase till the loop reaches S′, after which the current, always preserving the same direction, will diminish till the loop arrives at O′, when the current will for a moment fall to zero, to be succeeded by a current in the opposite direction as the loop leaves O′. This current will in like manner increase during the advance of the loop to N′, when it will attain a maximum, and afterwards diminish till it arrives at O, where, after passing through zero, the direction will again change. There will thus be a current always flowing in one direction as the loop moves from O through S′ to O′, and in an opposite direction as it moves from O′ through N′ to O. Now if the loop, instead of being moveable upon the ring, be firmly attached to it, and the ring itself carrying the loop be rotated on its axis in the plane of the fixed magnet N M S, it will be found that the currents developed will correspond both in direction and

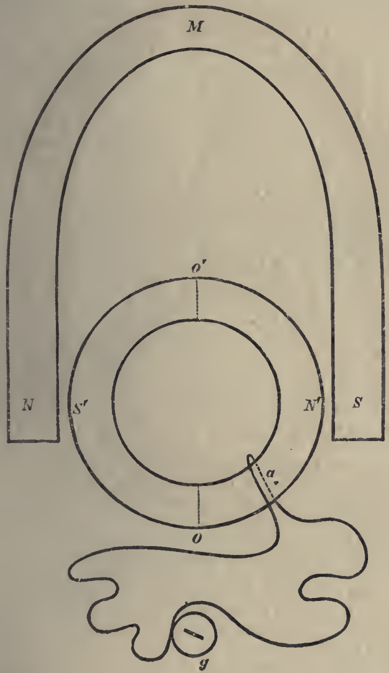

Fig. 5.

intensity with those produced in the moveable loop, provided we allow for the small displacement in the position of the poles of the ring arising from its motion.

The foregoing statement may be extended from a single loop to any number of loops forming part of a coil extending over the whole of the iron ring (Fig. 4). Each loop of such a coil, during one-half of every revolution, will tend to give a current in one direction, and during the other half, a current in the opposite direction, and the electromotive force thus produced will augment with the number of loops in the coil. If, then, metallic conductors, *c c*, *c′ c′*, are applied to the loops (whose surfaces must be exposed at one point for this purpose) as they pass through the positions O and O′, continuous currents, all in the same direction, will be obtained on rotating the ring without the use of a commutator, unless we apply that term (as Pacinotti has done) to the system of conductors or rheophori by which the currents are carried off.

In order to obtain currents of high intensity, the single coil must be replaced, as in similar machines, by a number of coils of thin wire rolled one above the other and carefully insulated. To carry off the current, these coils must be divided into separate helices, with the adjacent terminals of the wires of the helices in metallic connection, so that the iron ring may be always surrounded by an endless conductor of great length. I have already described the arrangements adopted in the transversal electro-magnet of Pacinotti. The construction of the ring armature in Gramme's machine will be readily understood from Fig. 6, in which it is represented in different stages of its construction, so as to show the manner in which the principal parts are connected.* At A a section of the iron ring itself is shown, composed of a bundle of iron wires; at B B the helices, or bobbins, are seen both in section and detached; and at R R the form is shown of one of the insulated copper conductors, to which the contiguous ends of the wires of the helices are attached, and from which the current is drawn off by means of rubbers or brushes formed of flexible bundles of copper wire. These brushes are so applied at the neutral positions of the ring that they begin to touch one of the conductors R, before they have left the preceding one. In this way no actual break or interruption occurs in the current. The permanent magnets employed in the smaller

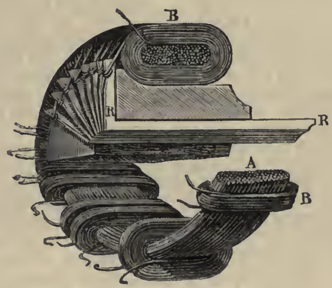

Fig. 6.—Gramme Armature.

Gramme machines are on the improved construction of M. Jamin.

With a small machine, on the Gramme construction, very remarkable electrical effects may be obtained. I will give the results of a few experiments which I recently made with one of the two machines exhibited at the late meeting of the British Association, and which are now in Queen's College, Belfast. This machine was able to heat to full ignition in daylight a platinum wire one foot in length, and weighing 12 grains. With a voltameter formed of two slips of platinum foil, exposing each a surface of 1·25 square inches, and at the distance of half an inch from each other, immersed in dilute sulphuric acid, water was freely decomposed. For 100 turns of the machine, the volumes of the mixed gases collected at different rates of turning were as follows:—

In	34 seconds	... ...	2·60 cubic inches
„	45 „	... ...	2·53 „
„	75 „	... ...	1·45 „
„	135 „	... ...	0·35 „

From these observations it appears that, under the conditions of this experiment, the quantity of water decomposed for the same number of revolutions of the ring increases quickly with the rate of the motion till a certain

* I take this opportunity of expressing my obligations to M. A. Niaudet-Breguet for his kindness in enabling me to give the admirable figures of the Gramme Machine which illustrate this paper. They first appeared in a short work on the Gramme Machine, recently published by M. Breguet, to which I beg to refer for more detailed information regarding its practical applications ("Machines Magnéto-électriques Gramme." Par M. A. Niaudet-Breguet. Paris, 1875).

rapidity is attained, after which little further change occurs.

An interesting experiment may be made with these machines, which illustrates a well-known dynamical principle, by turning the machine at a steady rate, with the wires for transmitting the current disconnected, and observing the great additional force required to maintain the motion on connecting the wires.

The machine may be converted into an electro-magnetic one by transmitting the current from a voltaic pile through the helices of the iron ring, which will then rotate upon its axis. If the current be supplied by another magneto-electric machine, the same result will be produced, and we shall thus have mechanical force, after assuming the form of current electricity, reappearing, but with some loss, in the form of mechanical force. In an experiment on the large scale described by M. Breguet, the loss amounted only to thirty per cent. If during this experiment the machine which supplies the current has its motion reversed, the other machine will soon come to rest, and afterwards begin to turn in the opposite direction. The intensity of the current, M. Breguet remarks, augments with the velocity of the rotation, the electromotive force having been proved by experiment to be proportional to the velocity. At first view it might appear that the resistance would remain constant; but as the intensity is found not to be proportional to the velocity of an invariable circuit, we are led to the conclusion that the resistance of the machine is not constant. This important point has been established by M. Sabine, but the details of his experiments have not been published. The increase of resistance is, however, so small, that a machine which gives with a velocity of 100 turns per minute a current equal to that of one small Bunsen's element, will give with a double velocity a current equal to two such elements a little larger, and with a quadruple velocity a current equal to four still larger elements of Bunsen. It is certain that this increase of electromotive force cannot be indefinite, but must tend towards a limit; but this limit does not appear to have been reached even with a velocity of 3,000 turns per minute.

(*To be continued.*)

ON THE TEMPERATURE OF THE HUMAN BODY DURING MOUNTAIN-CLIMBING

IN the year 1869 both Dr. Wm. Marcet, of Nice,* and Dr. Lortet, of Lyons,† published the results of thermometric experiments prosecuted by themselves on themselves during the ascent of Mont Blanc. Both physiologists discovered that during the act of ascent, if it were rapid and prolonged for any considerable time, the temperature of the body fell considerably, as much as 3·6° F. in the case of the English, and even 8·6° F. of the French observer. The temperature was taken in the mouth, and read off by means of a small reflector attached to the thermometer, which is a much more satisfactory manner of recording reducing temperatures than the employment of maximum registering instruments. Dr. Marcet tells us that in order to assure himself that the cooling of the body during the ascent was really due to the muscular effort, and not to the effect of the rarefaction of the air, he made one ascent (from Cormayeur to the plateau of Mont-Frety, about 2,440 yards high) partly on mule-back. After having gone two-thirds the distance, his temperature was 97·5° F., when, leaving the mule, he performed the rest of the journey on foot as quickly as possible. Just before arriving at the end, his temperature was not above 95° F., or 2·5° below what it was thirty-five minutes before, at the lower level. Another peculiarity observed by this author is that the body-temperature, after having diminished during an ascending walk, rapidly rose again upon rest being taken, or on the speed being reduced.

* "Archives des Sciences Physiques et Naturelles." 5e serie, t. xxxvi. p. 247. (Geneva.

† "Recherches Physiologiques sur le Climat des Montagnes" (Paris.)

All these unexpected results have, from the absence of fresh facts to throw light upon them, been but little discussed. It has been asked whether the above-described fall of temperature depends on the transformation of the energy of muscular action into work instead of, as usual, into heat in the body. The answer to this question is, however, not so easy as it might at first sight appear. If the exalted temperature of warm-blooded animals in a state of rest is the index of the amount of internal work done by the heart and the respiratory muscles, then extra muscular work will produce a proportionately greater rise of body-temperature, as it is employed in doing less external work, and the reverse; from which consideration it is rendered theoretically probable that the rise in temperature attending a rapid ascent of an incline would be much less considerable than that accompanying a similar effort which is attended by no external effect. In fact, the temperature of an individual in the act of throwing oranges forcibly away in all directions should be scarcely above the normal, whilst if he continually throws one up, again catching it, his temperature should rise considerably. In the one case the muscular effort is employed in heating the ground against which the moving oranges come in contact whilst being brought to rest; in the other case the energy lost to the body in the upward projection of the mass is regained in the form of heat when the muscles of the limbs resist its downward movement in catching it.

At this stage of the inquiry the elaborate investigations of Prof. Forel, of Lausanne,* prosecuted with indefatigable industry during the last four years, form an important addition to the literature of the subject. This physiologist, in a most painstaking and thorough manner, has investigated the whole problem, together with all the minor details associated with it: the results he has arrived at have consequently a wider interest than the simple solution of the question which originally led to their being commenced.

In his earlier series of experiments, Dr. Forel, whilst staying at the Rhone Glacier, at Zermatt and at the Lake of Geneva, ascended the Grimsel, the Riffel, and to Chigney, as well as to other neighbouring heights, in the end arriving at the following conclusions:—firstly, that the method of measuring the body-temperature in the mouth is not sufficiently precise for the study of the influence of muscular exercise on the general temperature of the body; and, secondly, that the act of ascending normally produced an *elevation* of the temperature of the body to the extent of several tenths of a degree, which diminishes during the subsequent repose, in tending to regain the normal standard.

These results, obtained in 1871, being directly at variance with those of Doctors Marcet and Lortet, Dr. Forel repeated his experiments with greater precision during the years 1873 and 1874. He commenced by determining the relative values of the different regions of the body in which it is possible to employ the thermometer for the estimation of the general temperature. More than a hundred observations in the floor of the mouth led him to reject that position for the thermometer, chiefly because it is next to impossible, during muscular exercise, to retain the mouth closed for any considerable time in a cold, dry, rarefied air. The palm of the hand, the arm-pit, and the external auditory meatus were rejected as being even less advantageous. The rectum was the last resource, and its advantages were found to be so great that all the most important results, to be mentioned directly, were arrived at from temperatures obtained in that situation.

The author commenced by forming a curve which repre-

* "Expériences sur la Température du corps Humain dans l'acte de l'ascension sur les Montagnes." (Geneva and Bale, 1871 and 1874.)

sents the average temperature of his own body at the different hours of the day, in order that he might eliminate this factor as a disturbing cause in his special observations. The curve represents an elevation of the temperature between the hours of 3 and 9 A.M., and a fall between 9 P.M. and 2 A.M., with an elevated temperature during the day, the undulations of which are far from constant and are difficult to characterise. In employing these results practically, Dr. Forel has introduced a method of turning them to account, which is as useful as it is precise and ingenious. In any special experiment, calling t the temperature, and T the normal temperature at the time of observation as found from the tabulated curve, then

$$t - T = t'$$

t' being the difference between the observed temperature and that which, under ordinary circumstances, it would be, either above or below it. As examples, we will take two given by the author :—

At 12 o'clock, noon, $T = 99{\cdot}09°$ F. On one particular occasion t was found to be $99{\cdot}5°$ F., and therefore

$$t - T = t' = + 0{\cdot}41° \text{ F.}$$

On a second occasion, at the same time of day, the temperature observed was $98{\cdot}78°$ F., from which it is evident that

$$t' = - 0{\cdot}31.$$

By the employment of this very simple means, therefore, the complications dependent on the time of day at which an observation is made may be immediately eliminated; all comparisons being between the different values of t', and not of t. Whether the assumption that the daily curve of body-temperature-change depends on the time of the day at which the observation is made, and on the time only, is a question into which the author does not enter, notwithstanding that such is the case has been by no means proved.

Turning now to the results arrived at from the investigation, the position in which the subject was left by Marcet and Lortet may be thus summarised :—

1. The temperature of the body, as a rule, falls during the act of ascending an incline.

2. During the time of the "mountain sickness," which so frequently accompanies the ascent of lofty heights, the body-temperature falls in a very marked manner.

Dr. Forel's earlier experiments, conducted in 1871, in which the thermometer was retained in the mouth, as was done by Marcet and Lortet, being directly opposite in their tendency, led him to commence the whole subject in 1872, as he remarks *ab ovo*, under his improved conditions.

As to the effect of an uncomplicated ascent, two instances are given in full, in both of which a considerable *rise* in temperature accompanied a rapid ascent of about an hour's duration. In one of these, at the end of the journey, the thermometer registered $102{\cdot}5°$ F., whereas it was slightly below 100° F. on starting.

In a second series, three illustrations are given of the effect of well-marked fatigue, just short of exhaustion. The following are the deductions drawn from them :—

1. Even in conditions of great fatigue, the human body rises in temperature upon the muscular effort of ascending a height.

2. It is impossible for the author to determine if the elevation of animal heat due to the movement of ascension diminishes in proportion to the increase of the muscular fatigue.

Next as to the influence of an empty stomach on the temperature curve; and it must be noted, with regard to this point, that both Marcet and Lortet have stated that the fall in temperature accompanying an ascent is more marked during a fast than shortly after a meal. On himself, Dr. Forel, however, again proves that a fast of twelve or even twenty-four hours is no obstacle whatever to the rise of temperature which attends the muscular effort of ascending a hill.

By collecting and comparing the temperature-curves produced in ascending and descending inclines, the author is enabled to verify the theoretical necessity that the body-temperature is raised more by a descent than by an ascent. From twenty-one experiments, the average rise in temperature attending the act of ascending is found to be $2{\cdot}412°$ F., whereas the mean of seven descents is found to be $2{\cdot}772°$ F. The difference, $0{\cdot}36°$ F., is small, it is true. If this fact is reliable, we find that a certain amount of heat is transformed into mechanical work during the act of ascent, a certain quantity being returned to the organism from without, under the opposite condition.

There are several minor points which Dr. Forel discusses in a particularly instructive manner, amongst which are the time of cooling after muscular exertion, the effect on the pulse and respiration of mountain climbing, and the cause of mountain sickness. He terminates his very interesting observations by the account of an ascent of Mont Rosa in July 1873 (15,217 feet), in which, notwithstanding that he suffered from mountain sickness, the body-temperature never showed any tendency to fall throughout, and was $101{\cdot}5°$ F. on his reaching the highest point.

From this summary of Dr. Forel's results, when taken in connection with those of Dr. Allbutt,* it is evident that the temperature-fall observed by Drs. Marcet and Lortet during mountain climbing requires re-verification, and cannot be accepted as a physiological fact until a fallacy has been shown to exist in the method of investigation adopted by the Swiss experimenter. A. H. G.

NOTES

AT Cairo, on the 2nd inst., the inaugural meeting took place of the Société Khédivale de Geographie, under the presidency of the eminent traveller Dr. Schweinfurth and the patronage of H.H. the Khedive, who has shown special favour to the young society, having placed at its disposal a handsome suite of apartments furnished in suitable style, and also presented a valuable library, besides subscribing 400*l*. a year to the funds. This cannot but be gratifying to the friends of science and progress, and is a hopeful sign for the future of Egypt and of the extensive region from which it claims allegiance. Let us hope that like results will follow the intercourse between this country and the Sovereign of Zanzibar. With these two African potentates on the side of progress, the advantages to knowledge, as well as to Africa, could not but be great. At all events, under the powerful patronage of the Khedive, this Egyptian Geographical Society is bound to make valuable contributions to our knowledge of North Africa. Dr. Schweinfurth, in his inaugural address, which was characterised by great fervour, spoke of the domain and progress of geography. "It has become," he said, "an immense domain, the meeting-place of all branches of human science. The geography of the present does not aim at merely describing the external form of the earth, the vesture which it has assumed; it seeks to show the chain of hidden causes of which this form is the expression." He then spoke of Africa and the great interest attaching to it, and especially to the Nile, the sources of which he believes contain the key to all the mysteries of Africa. Dr. Schweinfurth then referred to the history of Egypt and its progress under its present ruler, by whose special desire the Society has been organised. The motto of the Society, he said, should be *Nusquam otiosus*, and its duty *Centraliser et encourager*. After pointing out to those who take a "utilitarian" view of science, that all the comforts and commodities of modern life are due to researches which, though purely theoretical in their origin, have yielded magnificent practical results, Dr. Schweinfurth indicated the benefits to be gained from the increase of geographical know-

* *Journal of Anatomy and Physiology*, vol. xi. p. 106.

ledge, and described the organisation of the new Society and the task which lies before it. He showed what advantages a Society so situated had over European societies for extending our knowledge of Africa, and pointed out what yet remained to be done ere the topography of North Africa could be considered anything like completely known. We notice that the principal geographical societies of Europe and America have sent their congratulations to Dr. Schweinfurth on the founding of this Society; England's name, however, is not mentioned.

MR. MACLEAY, who has organised the expedition to New Guinea, our readers may remember, has already liberally endowed Sydney University. The ship he has fitted out for exploring New Guinea is a 400-ton man-of-war. His chief object is to enrich his Natural History collection, and he intends to do deep-sea dredging; he takes also a steam launch for ascending the rivers. There is one immense river, named the "Fly" River, after H.M.S. *Fly*, about which nothing is known. Mr. Macleay thinks that he will be able to ascend some 200 miles.

M. POLJAKOW, commissioned by the Russian Geographical Society, undertook a journey last year into the region of the Upper Volga, chiefly for zoological purposes, though he also obtained some important geologico-geographical results, an account of which appears in Heft vi. of Petermann's *Mittheilungen*. From the observations which he made, Poljakow concludes that the Scandinavian Finlandic glacier which once held in its fetters the government of Olonez and the neighbouring governments, must have stretched far into the basin of the Volga and over the boundaries of the Waldai plateau; and that by the unequal levels of the lakes formed by the melting of the glacier, the slender remains of which are seen in the existing lakes, undoubtedly a connection existed between the basin of the Volga and the Arctic and Baltic seas. Judging from the fauna, Poljakow concludes that the present upper course of the Volga must have been joined to the middle and lower course at a recent period and in a manner accidentally. The upper river has an entirely different and indeed a more northern water fauna than the middle and lower river. In this respect is the Scheksna to be considered the natural upper part of the Volga, for it contains the very same fishes as that river as far as Bjelosero.

DR. FOREL, of Lausanne, has for several years been investigating what are known as the *Seiches* of the Lake of Geneva. *Seiche* is applied locally to certain oscillatory movements which are occasionally seen to occur on the surface of the lake. The phenomenon had been investigated by previous observers, among others by Saussure and Vaucher, who attributed the phenomenon to variations in atmospheric pressure; in this, Forel, who has most minutely investigated the phenomenon, agrees with them. The phenomenon is found to occur on other Swiss lakes, and Forel believes it will be found in all large bodies of water. Indeed, he recognises in the *Seiche* probably the most considerable and the grandest oscillatory movement which can be studied on the surface of the globe. His investigations have led him to the conclusion that the *Seiche* on the Swiss lakes is an oscillatory undulation (*ondulation de balancement*), having a true rhythm, and that the phenomenon is not occasional, but constant, though varying in degree. The duration of a *Seiche* is a function of the length and depth of the section of the lake along which it oscillates; this duration increases directly with the length and inversely with the depth of the lake. The instrument he has devised for the investigation of the phenomenon he calls a *plémyramètre* ("tide-measurer"). A detailed account of Forel's investigations will be found in two papers in the *Bull. de la Soc. vaud. des Sciences Naturelles*, tomes xii. and xiii. Both papers have been republished separately.

HEFT VI. of Petermann's *Mittheilungen* contains a valuable paper by Vice-Admiral B. v. Wüllerstorf-Urbair on the Meteorological Observations made by the recent Austro-Hungarian Arctic Expedition, with an analysis of the ship's course. The paper is accompanied by a chart showing the drift of the ice, the course of the ship, the depths of soundings, the direction of the wind, and various other data.

AT the meeting of the Geographical Society on Monday, a lecture was delivered by Admiral Sir Leopold M'Clintock on "Arctic Sledge Travelling." After an account of the expeditions of former Arctic travellers, from Parry downwards, Sir Leopold gave a description of the appliances required for Arctic travelling, and of the difficulties to be encountered. To sledging, he said, we are indebted for almost all our Arctic experiences, and to sledging we shall owe the principal share of whatever work may be done by the brave men now going out. The greatest bar to their progress would be ice too thin to sledge over; sledge-bearing ice or open water their equipments will enable them to traverse.

AN opportunity will occur of sending letters for the Arctic ships *Alert* and *Discovery* by the exploring yacht *Pandora*, which will leave Portsmouth about the 23rd instant, Mr. Allen Young, commanding that vessel, having consented to receive letters, newspapers, &c., upon the chance of their being delivered to or deposited for those ships. No articles of value should be sent, and letters, &c., should be addressed to the General Post Office, and marked "Per exploring yacht *Pandora*."

A VERY full and interesting *résumé* of the progress of geographical discovery and of the sciences connected with geography, by M. Charles Maunoir, appears in the April number, just issued, of the *Bulletin* of the French Geographical Society; it is illustrated by a series of small maps. The same number contains the plan of a scientific journey into the interior of Indo-China, by Dr. J. Harmand.

NEW YORK telegrams of June 12 report a terrible earthquake in the Cucuta Valley, Republic of New Grenada. Cucuta, it is stated, has been entirely destroyed. Five other towns were nearly destroyed, and 16,000 persons are reported lost, out of a population of 35,000.

A TELEGRAM dated Barcelona, June 10, states that some shocks of earthquake had been felt there and in the neighbouring villages.

THE U.S. Hydrographic Office, of which Commodore R. H. Wyman, U.S.N., is superintendent, has commenced the systematic establishment of secondary meridians by telegraphic exchange of time-signals. Lieut.-Commander F. M. Green, U.S.N., is at present in charge of the work, and has during the past winter made observations at Panama, Colon, Kingston, Santiago di Cuba, and Havana. The starting-point used for the determination of longitude has been the meridian of Key West, Florida, established with great care by the U.S. Coast Survey. In addition to longitude observations, the latitude of each station has been determined with the zenith telescope. The work will be continued next winter through the Windward Islands to Guiana and Brazil. The liberal conduct of the companies owning the cables has much facilitated the successful prosecution of the work.

WE may see from the following extract from the New York *Nation* how very closely our doings on this side of the water are watched. The appointments referred to we have already announced in NATURE, but the comments upon them by the *Nation* indicate what we hope will be the method pursued by England in the course of time, though we fear the course will be a very long one. "Two recent appointments," the *Nation*

says, "in the University of Zürich seem to merit notice, as signs of the times. One is that of Prof. W. Wundt to the Chair of Philosophy, the other that of Prof. E. Hitzig to the Chair of Psychology. Wundt has long been occupied at Heidelberg, first as Assistant, then as 'Ordinary' Professor of Physiology, whilst Hitzig has been a medical practitioner and lecturer on electro-therapeutics in Berlin. So far as we know, the latter has written nothing on purely mental science. His discovery of the irritability of the surface of the brain is his chief title to fame; all that he has written shows erudition, great experimental thoroughness, and conscientiousness in drawing inferences. Wundt is one of the most learned of German investigators. His own special work has lain most in the line of the senses and the nervous system, the territory common to mind and matter; and all the elements of his training hitherto unite to make him an eminently well-qualified teacher of mental science. Indeed, we doubt not that his long apprenticeship in physiology was accepted by him merely that he might be the better educated for philosophy. In this country such appointments would probably provoke a good deal of orthodox alarm. But in Germany not only is thought more fearless of consequences, but 'camps' in opinion are much less clearly defined, and materialistic and spiritualistic tendencies keep house together most amicably in the same professional brains. We cannot help regarding such appointments as these as hopeful tokens of a new era in philosophical studies—an era in which the old jealousy between the subjective and the objective methods shall have disappeared, and in which it shall be admitted that the only hope of reaching *general* truths that all may accept is through the co-operation of all in the minute investigation of special mental processes. We may then see solid philosophical conclusions gradually emerging from the mass of discoveries of detail, just as happens in the sciences more especially recognised as 'inductive.'"

WE take the following from the *Athenæum*:—Mr. William Davis, who has been an attendant at the British Museum since 1843, but has practically fulfilled, for a long time past, duties requiring considerable scientific acquirements for a salary which, after the lapse of thirty years, had risen to the magnificent sum of some twenty-five shillings a week, was on Wednesday appointed by the Trustees an assistant in the Department of Geology. Mr. Davis was the first recipient of the Murchison Medal of the Geological Society, and is a well-known authority upon vertebrate fossils, especially fishes and mammalia.

THE series of papers on Portuguese Travel by Mr. John Latouche, which have appeared in the *New Quarterly Magazine*, are shortly to be published by Messrs. Ward, Lock, and Tyler, under the title of "Travels in Portugal," with illustrations by the Right Hon. T. Sotheron-Estcourt.

A TELEGRAM, dated "Strangway Springs, April 17," has been received from Mr. Ernest Giles, who has been exploring to the north of Fowler's Bay, Australia. He had had one long stretch of 220 miles without water; all the horses died, and he was only saved by his two camels. Mr. Lewis's expedition to Lake Hope, South Australia, has proved successful. Lake Hope he found perfectly dry. Before completing his work, Mr. Lewis purposes endeavouring to discover a route between the south-west portion of Queensland and the north-west of New South Wales, with a view of establishing direct overland communication with the former colony.

THE annual meeting of the Palestine Exploration Fund was held last Thursday. Since the Society was founded in 1865, four expeditions have been made, and surveys and excavations effected. The surveys have extended from Mount Carmel in the north to Beersheba in the south, and from Askelon in the west to the Dead Sea.

THE death of the lamented Rémusat has created a majority in favour of M. Dumas in the election which will take place at the Académie Française five months hence. It was owing to the prospect of a vacancy that the election was postponed when the Academicians were unable to agree after three successive meetings.

THE death is announced, on June 9, at the age of seventy-nine years, of M. Deshayes, Professor in the Paris Musum of Natural History.

La Revue Scientifique records the death, on May 11, at the age of thirty-two years, at Algiers, of a distinguished Mussulman chemist, Abdallah ben Mohammed. His mission was to instruct in the physical sciences, and especially in chemistry, the native Algerians; for this purpose he had to devise an Arabic terminology.

THE death is announced of Senhor Joaquim Henriques Fradesso da Silveira, director of the Meteorological Observatory of the Infanta Don Louis at Lisbon.

THE Professorship of Chemistry at Munich, we learn from the *British Medical Journal*, which has remained vacant since the death of Liebig, has been accepted by Prof. Baeyer of Strasburg, who will commence his duties next winter session.

THE jury of the Exhibition of the French Central Society of Horticulture has awarded a large gold medal to M. De la Bastie for his discovery of hardened glass, on account of the services it is likely to render to horticulture.

THE Annual Report of the United States Geological and Geographical Survey, describing the explorations of the year 1873, which has just reached us, contains, besides the descriptive letter-press, several valuable illustrations of some of the more recently discovered genera and species of Mammalia belonging to genera closely allied to Dinoceras (Marsh). These include *Symborodon bucco* (Cope), *S. Saltirostris*, and *S. ater*, all very peculiar forms.

WE have received the third Annual Report of the Zoological Society of Philadelphia, just published, which tells very strongly in favour of the institution. The additions by presentation and purchase are numerous, including six Giraffes, an Elk, an African and an Indian Elephant, and a Ka-Ka Parrot. We may judge that the Gardens are constantly kept in view by the citizens in their travels, from the fact that not less than twenty-three alligators were presented within three months.

THE President of the Italian Geographical Society has received favourable intelligence of the expedition sent to examine the possibility of conducting the waters of the sea into the hollow basins of the Sahara. The expedition will be divided into two parties at Gares. One is to explore the Oasis of Gerid, and carry out some interesting collateral researches among the ruins of Carthage, particularly the remains of the aqueducts and the remarkable lead mountain of Gebel Drucas.

AN attempt which has just been made to introduce living humming-birds into the Paris Jardin d'Acclimatation has failed, although a traveller managed to bring six alive to Paris by feeding them with honey. The only other humming-birds which have reached Europe alive were those brought by M. Delattre in 1855 from Central America, but these died a fortnight after their arrival in Paris.

"NURAGGHI SARDI, and other Non-historic Stone Structures of the Mediterranean Basin," is the title of an illustrated pamphlet by Capt. S. P. Oliver, who offers it "as a slight contribution towards the constantly increasing knowledge of those pre-historic remains which are scattered in mysterious groups throughout the Old World." Carson Brothers, of Dublin, are the publishers.

THE additions to the Zoological Society's Gardens during the past week include a Grant's Gazelle (*Gazella granti*) from East Africa, presented by Dr. Kirk; a Beccari's Cassowary (*Casuarius beccarii*) from New Guinea, presented by Sir James Fergusson; an Owen's Apteryx (*Apteryx oweni*), two Weka Rails (*Ocydromus australis*), a Black Wood Hen (*Ocydromus fuscus*), from New Zealand, presented by Dr. G. Hector; two Australian Cranes (*Grus australasiana*) from Australia, presented by the Acclimatisation Society of Wellington, New Zealand; a Brown Indian Antelope (*Tetraceros subquadricornutus*) from India, a Dufresne's Amazon (*Chrysotis dufresniana*) from South-east Brazil, four Vulturine Guinea Fowls (*Numida vulturina*) from East Africa, an Anaconda (*Eunectes murinus*) from South America, purchased.

RECENT PROGRESS IN OUR KNOWLEDGE OF THE CILIATE INFUSORIA *

I BELIEVE that the object contemplated by the addresses which it has been the custom of your Presidents to deliver year after year to the Fellows of the Linnean Society will be best fulfilled by making them as much as possible the exponent of recent progress in biological science. The admirable addresses with which my distinguished predecessor has during his long tenure of office so greatly enriched our journal, afford an example as regards the exposition of botanical research which may well be followed in biology generally. The field, however, which thus offers itself is so wide, the activity in almost every department so intense, that the necessity of restricting the exposition within a limited area becomes imperative if it be expected to produce anything like a definite picture instead of a vast assemblage of images confused and ill-defined by their very multiplicity and by the condensation which would be inseparable from their treatment.

While thus imposing on myself these necessary limits, it is almost at random that I have chosen for this year's address some account of the progress which has recently been made in our knowledge of the CILIATE INFUSORIA—a group of organisms whose very low position in the animal kingdom in no way lessens their interest for the philosophic biologist, or their significance in relation to general morphological laws.

To enable you to form a correct estimate of the value of recent researches, it may be well to bring before you in the first place, as shortly as possible, the chief steps which have led up to the present stand-point of our knowledge of these organisms.

It is scarcely necessary to remind you that the first important advance which during the present century was made in our knowledge of the Infusoria dates from the publication of the great work of Ehrenberg,* whose unrivalled industry opened up a new field of research when, by his expressive figures and well-constructed diagnoses, he made us acquainted with the external forms of whole hosts of microscopic organisms of which we had been hitherto entirely ignorant, or which were known only by such figures and descriptions as the earlier observers with their very imperfect microscopes were able to give us.

Ehrenberg, however, as we all know, did not content himself with pourtraying the external forms of the microscopic organisms to whose study he had devoted himself, but sought also to determine their internal structure, of which scarcely anything had been hitherto known. In this direction, no less than in the other, the perseverance of the celebrated microscopist never flagged; but, unfortunately, at the very commencement of his researches he slid into a misleading path, and was never again able to find the right one.

Everyone knows how Ehrenberg, in accordance with preconceived notions of the high organisation of *all* animals, attributed to the Infusoria a complicated structure; how, while he rightly distinguished them from the Rotiferæ with which they had been confounded by previous observers, he yet regarded them as intimately related to these representatives of a totally different type; and how, in attributing to them a complete alimentary canal with numerous gastric offsets, he took this feature as their most important character, and designated them by the name of *Polygastrica*. And it is probably a matter of surprise to many of us, that with the overwhelming mass of evidence which subsequent research has brought to bear against the truth of the polygastric theory, the great Prussian observer should still adhere with undiminished tenacity to his original views.

Among the authors who, since the publication of the "Infusionsthierchen" have contributed most to a correct estimate of the morphology, physiology, and systematic position of the Infusoria, the names of Von Siebold, Stein, Balbiani, Claparede, and Lachmann, and most recently, Haeckel, stand out conspicuous.

The first who from a strong position offered battle to the authority of Ehrenberg was Carl Theodor von Siebold.* Von Siebold rejected *in toto* the polygastric theory, and, so far from admitting a complexity in the organisation of the Infusoria, he regarded them as realising the conception of almost the very simplest form of life, and attributed to them the morphological value of a cell.

Let us see what is involved in this most significant comparison. The essential conception of a cell is, as you know, that of a more or less spherical mass of protoplasm with or without an external bounding membrane, and with an internal nucleus or differentiated and more or less condensed portion of the protoplasm. It was to a form of this kind that Siebold compared the body of an Infusorium. He called attention to the soft protoplasmic mass of which the body mainly consists; to the external firmer layer by which this is surrounded; and to the variously-shaped body differentiated in the protoplasm, to which Ehrenberg had gratuitously attributed the function of a male generative organ. Here then were, according to Siebold, the protoplasm body substance, the bounding membrane, and the nucleus of a true cell.

The morphological value thus attributed to the true Infusoria—under which were included the Flagellatæ—was extended by Siebold to Amœba and its allies, and to the whole assemblage so constituted he assigned the position of a primary group of the animal kingdom to which he gave the name of PROTOZOA, whose essential character was thus that of being unicellular animals. He then divided his Protozoa into those which had the faculty of emitting pseudopodial prolongations of their protoplasm (Amœba, &c.), and those in which the place of the pseudopodia was taken by vibratile cilia or by lash-like appendages. To the former he gave the name of *Rhizopoda*; to the latter he restricted that of *Infusoria*; and lastly he divided the Infusoria into the mouth-bearing, *Stomatoda* (Ciliata), and the mouthless, *Astomata* (Flagellata). From every point of view Von Siebold's conception of the morphology of the Protozoa, and his sketch of their classification, however much this may have been subsequently modified, must be regarded as marking out an epoch in the history of zoology.

Shortly after this the unicellular theory was strongly supported by Kölliker,† and received further confirmation from the researches of Stein,‡ who, however, was unable to accept it to its full extent. With an industry almost equal to that of Ehrenberg, Stein had the advantage of the more philosophic views of organisation which had emanated from the newer schools of biology, and to him we are indebted not only for more accurate views of the structure of the Infusoria, but for the first important contributions to our knowledge of their development; and though the opinion which he at one time entertained, that the true Acinetæ are only stages in the development of the higher Infusoria, has been abandoned by him, he has nevertheless demonstrated the presence in an early period of the development of certain species, of peculiar pseudopodial processes resembling the characteristic capitate appendages of the Acinetæ, an observation of importance in its bearing on the relations of these last to the true Infusoria. No doubt can remain, after Stein's observations, that the Infusoria in their young state have the morphological value of a simple cell, and it is only after their development has become advanced, and that a marked differentiation has begun to manifest itself in this primordial condition, that there can be any difficulty in accepting their absolute unicellularity.

About this time Balbiani drew attention to some very important phenomena in the life history of the Infusoria.§ It had been known even to the early observers that the Infusoria multiplied themselves by a process of spontaneous fission. They had been frequently observed in the act of transverse cleavage, and had also been noticed in what appeared to be a similar cleavage taking place in a longitudinal instead of a transverse direction. Balbiani, however, showed that this apparent longitudinal

‡ Stein, "Der Organismus der Infusionsthiere," 1867.

§ Balbiani, "Recherches sur les organes générateurs et la réproduction des Infusoires." *Comptes Rendus*, 1858, p. 383.

cleavage had in many cases an entirely different significance; that it was, in fact, not the cleavage of a single individual, but the conjugation of two distinct ones; and he connected this phenomenon with what he regarded as a true sexual act.

It was then known that besides the nucleus which occupied a conspicuous position in the protoplasmic mass, there existed in many Infusoria another differentiated body similar to the nucleus but smaller, and either in close contact with it or separated from it by a greater or less interval. To this body the ill-chosen name of "nucleolus" had been given. Now, Balbiani's observations led him to believe that under the influence of conjugation this so-called nucleolus underwent a change and developed in its interior a multitude of exceedingly minute filaments or rod-like bodies, to which he attributed the significance of spermatozoa; while at the same time the nucleus became divided into globular masses, which Balbiani regarded as eggs, and in which he believed he could recognise a germinal vesicle and germinal spot. We should thus, according to this interpretation, have in the Infusoria the two essential elements of sexual differentiation, the spermatozoa and the egg.

Stein, though differing from Balbiani in certain details, accepts in its general facts the sexual theory, and maintains the spermatic nature of the rod-like corpuscles to which the nucleolus appears to give rise. But however real may be the phenomena described by Balbiani and by Stein, the correctness of assigning to them a sexual significance may be called in question; and it is certain that subsequent observation has not tended to confirm the hypothesis that we have in the Infusoria true eggs fecundated by true spermatozoa.

Claparede and Lachmann, two able and indefatigable observers fresh from the school of the great anatomist Johan Müller, now entered the field, and their joint labours have given us a great work on the Infusoria.* In this an entirely new view of the morphology of the Infusoria has been introduced. Receding widely from the unicellular theory of Siebold, they approximate towards the views of Ehrenberg in assigning to the Infusoria a comparatively complex structure; but instead of adopting the polygastric theory of the Prussian microscopist, they attribute to the Infusoria a single well-defined gastric cavity occupying the whole of the space limited externally by the outer firm boundary walls of the softer protoplasmic mass; while this mass is regarded by them as nothing more than a sort of chyme by which the gastric cavity is filled. According to this view, the nearest relations of the Infusoria would be found among the zoophytes, and their proper systematic seat would be in the primary group of the Cœlenterata.

Though few zoologists will now be prepared to accept the conclusions of the Genevan naturalists, the cœlenterate relations of the Infusoria has recently found an advocate in Greeff.† In an elaborate memoir on the Vorticellæ, Greeff sees in the very well-marked distinction between the external or cortical layer and the internal soft body-substance, a proof of the views maintained by Claparede and Lachmann; and he considers this position still further confirmed by the presence in *Epistylis flavicans* of numerous oval or piriform, brilliant, well-defined capsules, which are generally distributed in pairs below the outer layer, and which, under the influence of a stimulus, emit a long filament, thus closely resembling the thread-cells so well known as characteristic elements in certain tissues of the Cœlenterata.

It must be here remarked that the presence of similar bodies in the Infusoria, where they have been described under the name of trichocysts, has long been known. Though varying in form, they all possess a more or less close resemblance to the thread-cells of the Cœlenterata. Their presence undoubtedly indicates a step upwards in the differentiation of the organism, but, as we shall presently see, it offers no valid argument against its unicellularity.

In his admirable "Principles of Comparative Anatomy,"‡ Gegenbaur expresses doubts as to the sexual nature of the reproductive phenomena of the Infusoria, and is disposed to regard the so-called embryo-sphere, to which the nucleus gives rise, in the light of a proliferous stolon, from which several zooids are in some cases thrown off. Arguing from the Acineta-like form of the young in the higher Infusoria, as shown by Stein, and comparing the transitory condition of this with the permanent condition of the true Acinetæ, he believes that we are justified in regarding the Acinetæ as the ancestral form from which the proper Infusoria have been derived. He further compares the contractile vesicle and its canals in the Infusoria with the water vascular system of the worms, and believes that a parentage with these higher forms is thus indicated. Gegenbaur, moreover, expresses himself strongly against the unicellular theory. He regards, however, the absence of distinct cell nuclei in the substance of the Infusoria as affording evidence of their composition out of several "Cytodes" or non-nucleated protoplasm masses rather than out of true nucleated cells.

Still more recently Bütschli has given us the results of observations on the conjugation of *Paramæcium aurelia.** He is led, however, to doubt the validity of the sexual interpretation of the conjugation. He found that in certain cases in *Paramæcium aurelia* and in *P. colpoda* the so-called spermatic capsule into which the nucleolus had become converted, had entirely disappeared without any evident change in the nucleus; and he concludes that fecundation of the bodies regarded by Balbiani as eggs cannot be here entertained. Indeed, he will not allow that we have evidence entitling us to regard the appearance of filaments in the interior of the nucleolus as affording any indication of true spermatozoa. He offers no explanation of this appearance, but he calls attention to the fact that both Balbiani and Stein noticed that in *transverse* division of the Infusoria—a phenomenon with which conjugation can have nothing to do—the nucleolus frequently enlarges and acquires a longitudinal striation like that of the nucleolus in the supposed production of spermatozoa during conjugation. Balbiani maintains that this striation during cleavage is only superficial, but it nevertheless affords an argument against assigning any more important significance to the very similar appearance in the case of conjugation.

On the whole it would appear that the spermatozoal nature of the striæ visible in the nucleolus of the conjugating individuals—even admitting that these striæ represent isolatable filaments—has not by any means been proved, while the phenomenon of conjugation in the Infusoria would seem to correspond rather with the conjugation so well known in many lower organisms, where it takes place without being in any way connected with the formation of true sexual products.

In the same memoir the results of observations on some other points in the structure and economy of the Infusoria have also been given by Bütschli. He records the occurrence of minute crystal-like laminæ in the interior of a marine Infusorium (*Strombidium sulcatum*) rendered remarkable by a conspicuous girdle of trichocysts which surround its body. The crystal-like corpuscles seem to be of the nature of starch, for on the application of iodine they assume a beautiful violet colour. It does not appear from Bütschli's account of these bodies that they have not been introduced from without, and the chief interest of the observation seems to be in the discovery of an amyllaceous body assuming a crystalline form. He had previously met with similar bodies in a parasitic Infusorium (*Nyctotherus ovalis*), as well as in a Gregarina (*G. blattarum*).

He also describes, under the name of *Polykricos Swartzii*, a new Infusorium which he frequently found in the fjords of the south coast of Norway and in the Gulf of Kiel, and which he regards as especially interesting, from the fact that with a true infusorial organisation it contains, irregularly distributed in the outer layer of the body, numerous capsules indistinguishable from the true cœlenterate thread cells. These bodies, however, are never included in a special investment, and he justly regards their presence as affording no argument against the unicellular nature of the Infusoria. He lays it down as a probable distinction between the trichocysts of the Infusoria and genuine thread-cells, that the former have the power of ejecting their contained filament from both ends of the capsule, while we know that in the thread cell it is only one end which gives exit to it. This double emission of a filament appears to have been observed by Bütschli in the trichocysts of a large Nassula, but the distinction is certainly not a generally valid one. There is no doubt that in the majority of cases the trichocyst emits its filament from only one end of its capsule, exactly as in the thread cells of the Cœlenterata, and it is hard to see in what respect the bodies noticed by Bütschli in his *Polykricos Swartzii* essentially differ from true infusorial trichocysts. In conlusion, he declares himself strongly in favour of the unicellularity of the Infusoria.

SCIENTIFIC SERIALS

THE current number of the *Journal of Anatomy and Physiology* contains much valuable scientific work, together with its excellent Reports on the progress of Anatomy and Physiology, by Prof. Turner and Dr. Stirling. The first paper is one on the freezing process for section-cutting, and on various methods of staining and mounting sections, by Mr. Lawson Tait. The author prefers the non-employment of chromic acid, picric acid, and other chemically-interfering agents. His section-cutter is a modification of Stirling's, a freezing tank of considerable size being added. The air-bubbles are removed from the sections by the action of boiled water. Logwood and litmus are preferred as staining agents, and their operation is given in proof of the nuclei of cells being, contrary to ordinary ideas, alkaline.—Prof. Flower, in a note on the construction and and arrangement of anatomical museums, makes several very valuable suggestions, which should be specially studied by those who have anything to do with the establishment and construction of biological museums. He shows how that in lofty rooms, with galleries, lighted at the ceiling-wall junction, the preparations have to be arranged according to their manner of preservation; dry, in bottles, and otherwise; which involves the separation of those illustrating any single subject. A series of small side-lighted rooms allows of all the specimens illustrating any single subject, however preserved, being placed in juxtaposition, whilst it separates off the subjects.—Dr. Hollis remarks, with several interesting historical references, on lopsided generation.—The next paper is by Mr. Walter Pye, entitled observations on the development and structure of the kidney. The relation of the capsule to the Malpighian tuft is explained upon the peculiarities observed in the developing organ in a manner differing from the results of Riedel. The characters of the ascending limbs of Henle's loops are described in detail. A plate accompanies the paper.—Mr. Lowne, in a note on the mechanical work of respiration, desires to prove that the amount of work performed in the respiratory act is much less than is usually stated, from calculations based on the relation between the velocity of moving gases and the pressure producing motion.—Dr. Howden describes a case of atrophy of the right hemisphere of the cerebrum attended with the same condition of the left side of the cerebellum and the left side of the body, in a woman aged 30.—Prof. Turner figures and describes the Spiny Shark (*Echinorhinus spinosus*) from a specimen captured near Bass Rock, six-and-a-half feet long. The ureters were found to open into the cloaca by a single orifice. There was no cement gland in the oviduct, from which it is evident that the ova have no horny case. The stomach is succeeded by a pyloric tube; pyloric cæca are absent. In comparing *Læmargus* and *Echinorhinus*, which are supposed to be closely related, it is found that the former possesses two large duodenal cæca and no oviducts, whilst in the latter cæca are absent and oviducts developed. Prof. Turner also proves, from a specimen caught off the mouth of the Frith of Forth, that the Postbeagle Shark (*Lamna cornubica*) possesses a spiracle, contrary to the opinion of most authorities.—Mr. D. J. Cunningham gives notes on the Great Splanchnic Ganglion. In twenty-six cases, he failed to detect its presence in six; it is situated on the body of the twelfth dorsal vertebra; it is variable in shape and size. The same author describes a case of lateral curvature of the spine in connection with hypertrophy of the sympathetic nervous system in the lumbar and sacral regions.—Mr. Dwight makes remarks on the position of the femur and on its so-called "true neck."—Drs. Kronecker and Stirling describe in detail experiments on the characteristic sign of cardiac muscular movement. The fundamental fact on which the investigation is based is the law of Bowditch, that "the induction current of the weakest strength which produces a contraction of the heart does not produce the weakest of possible contractions." The fact that after a pulsation has been developed in the heart of a frog, by a certain stimulation, the organ can be made to continue its beating with a diminished stimulus, is compared to the difference between the effort first required to sound a big bell and that necessary to maintain it ringing. The effect of temperature on the cardiac irritability is shown, the heart reaching its maximum mobility at 25° C. After the discussion of the difficult phenomenon of cardiac tetanus, the authors prove that "the cardiac muscles can only act equally with the help of continually new nutrient fluid." The paper is deserving of the attention of all physiologists.—Dr. Kronecker also describes a new digestion-oven with a diffusion apparatus.—Mr. J. C. Ewart has a note on a large organised cyst in the subdural space.—Mr. J. Reoch writes on the decomposition of urea, adducing evidence to show that in urine the urea is changed into carbonate of ammonia by the action of a fungus the germs of which are contained in the atmosphere.—Mr. M. Simpson describes the existence of two precaval veins in a dog, a condition constant in the kangaroo and some other animals.

Report of the Rugby School Natural History Society for the Year 1874.—We are glad to be able to say that this Report is a satisfactory one; all the sections have done a fair quantity of good work, and a large proportion of the papers read has been the work of actual members or associates. The papers are all highly creditable to the authors, and many of them give evidence of well-trained powers of observation. Mr. J. M. Wilson contributes three interesting papers. One, "On the construction of a geological model of the neighbourhood of Rugby," contains some queries and suggestions as to how such a work should be gone about, and we are glad to see that the model has actually been commenced and has already made considerable progress. This is really most profitable work on which to employ the members of the Society. Other papers by Mr. Wilson are, "On the companion of Sirius," a note of an observation on the *comes* of Sirius, from which Mr. Wilson infers that it has performed twenty-three degrees of its revolution in ten years; and "On the Geology of Hillmorton." The following titles of papers by members will give an idea of the work done by the Society:—"On Mounting for the Microscope," by E. J. Power; "On the Will-o'-the-Wisp," by H. W. Trott; "On Owls," by H. Vicars; "On the Sub-Wealden Explorations," by R. D. Oldham; "On an Entomological Expedition," by H. F. Wilson, who also contributes a paper "On the Great Spotted Woodpecker;" "On Migrations," by W. C. Marshall; "On Bees," by H. Vicars; "On Roman Remains near Church Lawford," by L. Knowles; "On Drops of Liquid," by H. F. Newall, a very interesting paper, giving evidence of some faculty for original research; "On Cuckoos," by W. Larden. Mr. Newall's paper on drops is illustrated by some carefully executed drawings. The same member has constructed an ingenious compound pendulum machine, an illustration of which is given, as also illustrations of some most delicate curves executed by the machine. Among other illustrations we may mention a heliotype copy of a drawing by J. H. Patry of fifteen various observations of the planet Mars, taken at the Temple Observatory. Very full sectional reports are appended, and under the head of "Statistics" a variety of information is given. Altogether this is one of the most satisfactory reports published by this Society.

Zeitschrift der Oesterreichischen Gesellschaft für Meteorologie, April 15.—This number contains an article by Prof. Buys-Ballot on the climate of Buenos Ayres, and another on the hailstones which have occurred in Würtemberg during the forty-six years 1828–73.

Bulletin de l'Académie Royale des Sciences de Belgique, 2 ser. t. xxxix. No. 3.—This number contains a note on *Pecopteris odontopteroides* (Morris), by M. François Crépin. There is a fossil from the coal measures of Hobart Town among those sent by Mr. Allport to the museum, which M. Crépin refers to the same species as that named by Prof. Morris. He doubts, however, whether Prof. Morris has assigned his specimen to its true relationships, believes it is nearer to *Odontopteris alpina* (Gein), and provisionally proposes *Odontopteris Morisii* as its name.—On the *calcaire carbonifère* between Tournai and the environs of Namur, by M. E. Dupont; a description of forty-seven pages, with two coloured folding plates of sections.—Researches on the structure of the corda dorsalis of Amphioxus, by M. Camille Moreau. The work was carried on in the microscopical laboratory of the University of Liége, under the direction of Prof. E. Van Beneden. The paper consists of a description with a plate. To complete the working out of the homologues of the layers, further embryological observations, M. Moreau says, are necessary.—No. 4. The communications in this number are:—Note on the temperature of the winter of 1874–75, by M. Quetelet. The winter is compared with that of 1859–60, and a table showing the resemblance is given.—Note on the halo with mock moons of March 23, 1875, by M. Chas. Hooreman.—On the theory of the use of hot air in furnaces, by M. H. Valérius.—On some fossil plants from the "Psammites du Condroz," by M. A. Gilkinet. This paper is partly of criticism on the work of M. Crépin, and is partly descriptive. Three folding plates of illustrations are given.

Archives des Sciences Physiques et Naturelles, vol. 52, No. 207 (March 15, 1875).—This part contains many papers trans-

lated and reprinted from other serials, besides several original ones. We note the following:—On the fossil vertebrata of the State of Nebraska, by M. Delafontaine. On the measurement of altitudes in Switzerland, executed by MM. Hirsch and Plantamour. On the action of galvanic currents upon alloys or amalgama, by M. Eugène Obach. On some experiments with Holtz's machine, by F. Rossetti. Researches on the spectrum of chlorophyll, by J. Chautard.

SOCIETIES AND ACADEMIES

London

Linnean Society, June 3.—Dr. G. J. Allman, F.R.S., president, in the chair.—The President nominated the following gentlemen as Vice-presidents for the ensuing year, viz.:—Mr. G. Bentham, F.R.S.; Mr. G. Busk, F.R.S.; Dr. J. G. Jeffreys, F.R.S.; and Dr. J. D. Hooker, P.R.S.—Prof. Thiselton Dyer exhibited, under the microscope, some specimens of the very rare Alga *Stephanosphæra pluvialis*, known to occur only in a single locality in Britain, a pool on Bray Head, in Ireland.—Dr. Trimen exhibited specimens of two recent additions to the British flora, *Zannichellia polycarpa*, found by Dr. Boswell-Syme in the Orkney Islands in 1847, and *Carex ornithopoda*, discovered by two working men in Derbyshire.—Mr. Pascoe exhibited a very fine collection of Crustacea from the Bay of Naples. The following papers were then read:—On the Barringtoniaceæ, by J. Miers, F.R.S. The purpose of this paper is to show that the Barringtoniaceæ constitute a distinct order, forming an extremely natural group with peculiar and uniform characters, differing from the Myrtaceæ in their alternate leaves without pellucid dots, and in the nature of their inflorescence and fruit. They are trees, frequently of large size, rarely low shrubs, all delighting in running streams, some growing in estuaries or along the sea-shore. The author describes the characters of the order in considerable detail, and gives the diagnosis—in many cases redrawn from actual examination—of each genus and species. The number of genera he makes to be ten. The paper was accompanied with drawings illustrating the floral and carpological characters of each genus.—Note on the occurrence of fairy rings, by Dr. J. H. Gilbert, F.R.S. This paper was founded on the observations made by the author and Mr. Lawes on their experimental plots at Rothamstead. After some particulars as to the effect of different manures in varying the proportion of different kinds of vegetation in permanent pasture, especially grasses and Leguminosæ, the author suggests that the determination of the source of the nitrogen in the fungi that constitute the fairy rings which frequently make their appearance on the plots would throw some light on the much-disputed question of the source of the nitrogen of the Leguminosæ. It is remarkable that although, according to published analyses of various fungi, from one-fourth to one-third of their dry substance consists of albuminoids or nitrogenous matter, and 8 to 10 per cent. of mineral matters or ash, of which about 80 per cent. is potassium phosphate; yet the fungi develop into "fairy rings" only on the plots poorest in nitrogen and poorest in potash. The questions which appear still to require solution are these:—(1) Is the greater prevalence of fungi under such circumstances due to the manurial conditions themselves being directly favourable to their growth? or (2) Are the lower orders of plants—in consequence of other plants and especially grasses growing so sluggishly under such conditions—better able to overcome the competition and to assert themselves? (3) Do the fungi prevail simply in virtue of the absence of adverse and vigorous competition, or to a greater or less extent as parasites, and so at the expense of the sluggish underground growth of the plants in association with them? or (4) Have these plants the power of assimilating nitrogen in some form from the atmosphere; or in some form or condition of distribution within the soil, not available, at least when in competition, to the plants growing in association with them?—On a possibly wild form of *Hibiscus Rosa-sinensis*, by Prof. Oliver, F.R.S.

Mathematical Society, June 10.—Prof. H. J. S. Smith, F.R.S., president, in the chair.—Prof. Cayley, F.R.S., made a brief communication on some figures of curves in 3-bar motion.—Prof. Sylvester, F.R.S., spoke on "James Watt's parallel motion," and on an apparatus for regulating the motion of a train of prisms.—Mr. T. Cotterill read a paper on the correspondence of points collinear with a fixed origin. In the paper S and T are taken homogeneous functions of any number of variables (say three, $x\ y\ z$): the degree of S being one lower than that of T, and are supposed to be connected with another set, $x'\ y'\ z'$, of the same number of variables by the equations $\frac{x'}{x} = \frac{y'}{y} = \frac{z' S}{T}$. If the variables $x\ y\ z$, $x'\ y'\ z'$, denote the co-ordinates of two points in a plane, a correspondence is established between them depending on the forms of S and T. The object of the paper is to explain the relations between the corresponding curves and to give examples.

Physical Society, June 12.—Prof. Gladstone, F.R.S., president, in the chair.—Lord Lindsay, Sir W. Thomson, and Prof. Sylvester were elected members.—Mr. Wildman Whitehouse described some experiments he had made on the electric conductivity of glass. He employed pieces of thermometer tube about an inch in length, into the bore of which two platinum wires were inserted in such a manner that there was an interval between the points. In some cases one wire of platinum occupied the entire bore of the tube, and this tube was surrounded on its external surface by a helix of wire of the same metal. In each case the arrangement was introduced into a circuit in which were also placed a Thomson galvanometer and a set of resistance coils. It was shown that at the ordinary temperature there was no deflection, but that the current passed freely when the glass was heated to redness. The difficulty of making contact with the glass led Mr. Whitehouse to use two test-tubes, one inside the other, both containing mercury, with which wires of platinum freely communicated. The flame of a Bunsen burner was applied to the outer test-tube and the temperature of the metal noted by the aid of a thermometer. In one series of experiments the diameter of the internal tube was $\frac{5}{8}$ inch, the length in contact with the mercury about $3\frac{3}{4}$ inches, and the thickness of the glass $\frac{1}{100}$th of an inch. A current was first observed to pass at 100° C., and, as the temperature rose, the amount of deflection increased. The following are approximate measurements of the resistance of the glass at different temperatures:—

At 165° C.	Resistance	= 229,500	Ohmads
,, 185 ,,	,,	= 100,000	,,
,, 210 ,,	,,	= 69,000	,,
,, 255 ,,	,,	= 22,500	,,
,, 270 ,,	,,	= 9,000	,,
,, 300 ,,	,,	= 6,800	,,

Prof. Gladstone drew attention to the necessity for ascertaining the nature and composition of the glass.—Prof. Guthrie alluded to the fact that electricity of high tension is freely conducted by glass at a red heat. He also asked whether, as the temperature was raised, a point was reached at which the conductivity began to decrease.—Prof. M'Leod pointed out that the thermometer tubes used by Mr. Whitehouse were of lead glass, and that the lead had in most cases been reduced by exposure to the flame of the Bunsen burner, and he urged that these facts should not be overlooked in measuring the resistances. He stated that lead glass is better than other kinds of glass for insulation.—Prof. G. C. Foster asked whether an increased capacity due to the heating might not introduce an error into the measurements of resistance. Mr. Whitehouse replied that he had only recently commenced the experiments, and promised that the suggestions which had been made should receive due attention.—The President then read a paper on the time required for double decomposition of salts. It is well known that if, on mixing solutions of two salts, MR and $M'R'$, an insoluble body can be produced by an interchange of metals and radicals, that body is produced to the fullest extent possible. The only explanation of this fact which has been given is founded on the theory of Bertholet, that in all cases of mixture there is a redistribution of the constituents according to their relative affinity and mass, with the production of more or less MR' and $M'R$. Now, if one of these, say MR', be insoluble, it will remove itself at once from the sphere of action, but this will necessitate a fresh distribution of the constituents with the production of more insoluble salt, and so on until the whole of the M has entered into combination with R'. Dr. Gladstone commenced this research twenty years ago, and added in a note to a paper in the Phil. Trans.: "It is easily conceivable that when the affinity for each other of the two substances that produce the insoluble compound is very weak, the action may last some time and become evident to our senses. Is not this actually the case when sulphate of lime in solution is added to nitrate of strontia, or carbonate of soda to chloride of calcium, or an alkaline carbonate to tartrate of yttria, or oxalate of

ammonia to sulphate of magnesia, &c.?"—The President gave several experimental illustrations of the time required for double decomposition. He showed that ferric chloride and sulphocyanide of potassium react instantly, that citrate of iron and meconic acid, chloride of platinum and iodide of potassium, react gradually. The rate of change really depends on the degree of rapidity of the inter-diffusion of the salts. It is also affected to a very great extent by temperature. The following numbers illustrate the rate at which sulphate of strontium is deposited on the addition of sulphate of calcium to a solution of nitrate of strontium. :—

The total amount of salt which could be formed being 1·5 grms.

Astronomical Society, June 11.—Prof. Adams, president, in the chair.—Mr. Lecky explained the use of two ancient instruments he had given to the Society. The smaller one was known as a night dial; it was used about the end of the sixteenth century for finding the time at night by the position of the pointers of the Great Bear. The observer stood with his face to the north, and the instrument was held in one hand, so that a line upon it was by estimation vertical to the horizon; and with the other a moveable arm like a clock hand was turned until it was parallel to the direction of the pointers. The time was then read upon the circumference of a boxwood circle, which had to be set afresh for every night of the year. The other instrument was a Backstaff, which was used at sea until the invention of the sextant for determining the sun's altitude. The observer in using it stood with his back to the sun (whence its name), and he measured the arc between the sun's place and the opposite horizon through the zenith. The instrument which was in use before this was a very simple contrivance, being merely a pole along which a moveable bar at right-angles was shifted, until the cross-bar subtended the same angle when looked at by the observer with his eye at the end of the pole as the sun's altitude. Such contrivances were called Forestaffs, and were in use at sea until 1591, when Capt. Davis invented the Backstaff.—Mr. Marth exhibited a drawing of the orbits of the satellites of Saturn as they will be seen from the earth about the middle of August next, when there will be a conjunction of the satellite Iapitus with the ring and ball of Saturn. Mr. Marth was anxious that observations of this conjunction should be made by the possessors of large telescopes, in order to afford data for the improvement of the theory of the satellites of Saturn.—A paper was read by Mr. Knobel on an instrument for determining the magnitudes of stars.—Mr. Christie said that the probable error in determining the magnitude of a star with his photometer amounted to only the twentieth of a magnitude, but that the probable error varied for stars of different colours, owing to the effect of contrast with the light of the sky, which caused a red star to be more easily distinguished when its light was diminished than a star with a blue tinge.

Anthropological Institute, June 8.—Col. A. Lane-Fox, president, in the chair.—Capt. Richard F. Burton, H.M. Consul at Trieste, read two papers on Ancient Remains in Dalmatia, viz., "The Long Wall of Salona" and "The ruined cities of Pharia and Gelsa di Lesina." Salona was the Roman metropolis of Dalmatia, of which southernmost province of Austria, Spalato was at present the natural, and Zara the artificial and political capital. The "long wall" was of doubtful and debated origin, and a reference to numerous ancient and a few modern writers on it was made to show the obscurity in which it still remains. The author gave an account of his explorations, with detailed measurements of the ancient structure, called by some "Cyclopean," and especially pointed out the great variety of stone dressing it presented, which would afford valuable evidence in determining the style and perhaps the date of the work. His conviction that the long wall of Salona was Greek and pre-Roman rested very much upon the fact that similar constructions exist in the neighbourhood. In the island of Lesina the two ruins visited and described by Capt. Burton presented a remarkable resemblance, amounting almost to identity, to the long wall of Salona, and suggested that they were all the work of a single people, and that people not the barbarous Illyrians, but the comparatively civilised Greeks. Only two flint implements had been found, and those were discovered at Salona, near Spalato. The exploration of the Dalmatian Islands was attended with much difficulty; the scarcity of water was an evil to be met, and a Slavic guide was necessary unless the traveller could himself speak Slavic, for the inhabitants all belong to that race. The islands never having been previously explored (as far as the author was aware) by Englishmen, there was a large field of research for the antiquarian as well as the more general anthropologist.

PARIS

Academy of Sciences, June 7.—M. Frémy in the chair.—The following papers were read:—On the different effects produced by the same temperature upon the same species of plants, in the north and in the south, by M. A. de Candolle.—Researches on magnetic rotatory polarisation, by M. Henri Becquerel.—On a new method and a new instrument for telemetry (quick measurement of distances), by M. Giraud Teulon.—On the transformation of the camphor of *Laurineæ* into camphene, and reciprocally of the camphenes into camphor, by M. J. Riban.—A note, by M. J. Ponomareff, on thiammeline, a new derivative of persulphocyanogen.—On the dissociation of sulphocarbonate of potassium in the presence of ammonia salts, by M. Rommier.—On the theory of revolution surfaces which, by way of deformation, can be superposed on one another, and each on itself in all its parts, by M. F. Reech.—Communications on Phylloxera, by several gentlemen.—Several papers of minor interest, competing for the prize of Medicine and Surgery.—On the geographical position of the island of St. Paul, by M. Mouchez; he finds the latitude to be 38° 42′ 50″·796 S. (with a probable error of 0″·03), and the longitude, 5h. 0m. 49s. (probable error, 4s.).—On fluorene and the alcohol derived from the same, by M. Ph. Barbier.—Researches on taurine, by M. R. Engel.—On the bibromide of angelic acid, by M. E. Demarcay.—On three observations of accidents from lightning, by M. Passot.—Analysis of the mineral coal of the Suderoe Island (one of the Faroes), by MM. Bechin and Ch. Mène.—Remarks by M. Tresca, on a projected atmospheric post between Paris and Versailles.—A note by M. Emm. Liais, on the parallax of the sun.—M. Vibraye then drew the Academy's attention to the apparition of a destructive hemipterous insect in the vineyards of the Loir et Cher Department. The insect is very similar to *Phytocoris gothicus*.—Remarks by M. J. de Cossigny, on waterspouts.—On a new propeller of steamships, by M. E. Lehman.

CROLL'S "CLIMATE AND TIME" *

Climate and Time in their Geological Relations; a theory of Secular Changes of the Earth's Climate. By James Croll, of H.M. Geological Survey of Scotland. (London: Daldy, Isbister, and Co., 1875.)

II.

MR. CROLL'S own theory about the distribution of heat by means of ocean currents is in intimate connection with his ideas as to the variation of climate in past time. His theory may be summarised as follows:—The Gulf Stream and other warm or cold currents are due entirely to the prevailing system of winds, which force the water along the surface, or even make it take a lower course; the return of the colder water from the Arctic regions being assisted by the difference of level caused by driving up the waters into a narrow basin, such as he supposes those regions to be. The result of this theory is, that if one hemisphere is colder than the other, the trades on that hemisphere will be strongest, and the resulting warm current will flow into the warmer hemisphere; any difference, therefore, in the mean temperature of one hemisphere from that of the other is augmented according to this theory by ocean circulation, whereas on Dr. Carpenter's theory the latter would have a counteracting influence. When, however, we take both theories into account, and also the effect of the distribution of land and sea, which is remarkably manifested by the two facts of the South Atlantic being coldest and the North Pacific also coldest, we see that we are not in a position to estimate the effect, if any of much consequence, of the different forms of ocean circulation on the occurrence of a glacial epoch, but must look for the causes of the latter independently.

Now what are the known facts to be explained? They are well described in various parts of this book, and the proofs of the less known are carefully given. We have first the widespread indications of a sheet of land ice in the northern hemisphere, reaching in some parts far down into temperate, if not into tropical regions; secondly, similar indications in the southern hemisphere during the same geological period, but without any proof of their being contemporaneous even in centuries with those in the northern; thirdly, a much milder climate than at present prevailing in very high latitudes in comparatively modern geological periods, though anterior to the glacial epoch; fourthly, that these changes from more intense cold to more intense heat have been going on throughout the whole of geological time; and lastly, that in the midst even of the glacial epoch, warm interglacial periods occurred. No satisfactory theory of the cause of the glacial epoch can leave any of these facts unaccounted for, still less contradicted. Sir Charles Lyell's theory, referring it to an alteration of the distribution of land and sea, does not well adapt itself to the magnitude of the phenomena indicated above in the first and second facts, and requires very sudden and violent changes to account for the fifth; and, moreover, it is shown by Mr. Croll that the distribution he indicates would have the very opposite effect to that supposed; geologists are therefore driven, however reluctantly, to consider the action of cosmical causes. Four theories founded on such causes have been proposed.

The first, that the solar system was passing through a cold region of space, may be dismissed at once; the second is that the sun is a variable star, and therefore the amount of heat received from him is variable; the third is, that the glacial epoch was due to a great obliquity of the ecliptic; and the fourth, Mr. Croll's, is that it depended on an increased eccentricity of the orbit combined with aphelion winters. We will discuss the last theory first, and examine Mr. Croll's proofs of it. In order to show how the eccentricity has varied in past time, and to find the periods at which it was a maximum or minimum, Mr. Croll has calculated by means of Leverrier's formula what its amount has been or will be, from 3,000,000 years past time to 1,000,000 years in the future, for intervals of 50,000 years, and has given a diagram and tables to illustrate the result. This must have been a most laborious task, but we are sorry to say that the results require confirmation. We have repeated the calculations for two of the most remarkable dates, near which the change is represented by Mr. Croll as very rapid from a maximum to a minimum, viz., 850,000 and 900,000 years ago respectively, and find that at the former date the eccentricity was ·0697 instead of ·0747, and at the latter date was ·0278 instead of ·0102 as expressed in the table. To satisfy ourselves that the mistakes are Mr. Croll's and not ours, we have recalculated also one of Mr. Stone's and one of M. Leverrier's results which have been used by Mr. Croll for the completion of his table, and in both instances have exactly verified them. The fact that the eccentricity was large when he represents it so, and small when he makes it small, seems to indicate that some approximating progress has been followed, and that possibly his diagram may give a *rough* idea of the changes of eccentricity for past time, provided of course that we agree to Leverrier's formula being used for such remote periods.

Assuming, however, that at some past date the eccentricity of the earth's orbit approached its maximum value, and that at the same time the winter of one hemisphere occurred in aphelion, what would be the result? In the first place the total annual heat received from the sun, which varies inversely as the minor axis of the earth's orbit, would be slightly increased, but not sufficiently to have much effect upon climate. The more important result would be that the hemisphere whose winter was in aphelion would have it very rigorous, and its summers would be very hot, while the other hemisphere would be enjoying a perpetual summer. It is on this that Mr. Croll relies for producing a glacial epoch, and we see that it involves the statement that the two hemispheres were *not* glaciated at the same time, while the other theories assume that they were.

Our question therefore is: Will an extreme difference between the winter and summer temperature produce a glacial epoch? The actual amount of heat received by either hemisphere may easily be shown to be the same, whether there are great or little differences between summer and winter, whether as to their length or their intensity, so that a glacial epoch could not be the *direct*

* Continued from p. 123.

result, and we must look to the indirect effects. While agreeing in the existence of many of those pointed out by Mr. Croll, we cannot think it quite so settled a matter as he does, as they do not all act in the same way. In the first place, though the total amounts of summer and winter heat together are equal in the two hemispheres, yet, since a larger proportion of the greater summer heat is *available* than of the smaller winter heat, the more unequal these are, it follows generally that *more* heat must be obtained, and therefore the more uniformly heated hemisphere will be coldest; but secondly, as Mr. Croll states, we must consider the formation of snow, *i.e.* take into account the latent heat of water and other physical properties. Some of his arguments on this point are rather circular, for whatever amount of heat is rendered latent in the melting of ice, as much will be supplied to radiation in the freezing; and no *increase* of ice would arise from this. There are, however, two points that seem to be made out. First, that snow and ice are better reflectors of light than almost any other substance, and therefore less heat enters into them; and, secondly, that moist air is much less transparent to heat than dry, so that the vapour raised by the sun in summer would be an *opposing* influence, whereas the frozen vapour in winter when fallen as snow would leave the air above freer for radiation. This result would overbalance that spoken of in the first place, and be a powerful influence in the production of a glacial epoch. The vapour, too, that was raised in summer would come in a large degree from the warmer tropics, and therefore continue to add each winter to the mass of the snow and ice in the more polar regions.

These seem to us to be among the most convincing of Mr. Croll's arguments, and they are in agreement, as he shows, with the condition of the earth at the present time as regards the more glaciated condition of the southern hemisphere, and they agree with what has been pointed out by Prof. Tyndall, that heat, to bring the snow in form of vapour, is just as necessary for a glacial epoch as cold to freeze it when brought. It has been argued by Mr. Murphy that under exactly the same circumstances it would be the more equally heated hemisphere that would be glaciated, as the cool summer would melt less snow; but according to the above theory the summer of the other hemisphere, though naturally hotter, would also be rendered cool at the earth's surface. We see that the whole of this argument depends on the relation of the atmosphere to heat rays, and what has been stated above has been experimentally verified; yet we are far from being fully informed on this point, and the example of the planet Mars, which is almost exactly under the circumstances of great eccentricity and winter aphelion supposed above, and yet has not much glaciation, teaches us that this may depend on other combinations of circumstances beyond those we have considered above.

The glaciation, Mr. Croll thinks, would be assisted by the deflection of ocean currents, on which he accordingly spends his strength; but the vertical circulation of Dr. Carpenter, no less proved than the influence of the Gulf Stream, would be antagonistic to this, and we may safely leave the unknown residuum out of consideration.

Such is Mr. Croll's theory of the cause of the glacial epoch, to the illustration of which he brings forward many interesting facts. Among these are the proofs he gives of the occurrence of warm interglacial periods. Some of these proofs are collected from other writers, but many are from his own observations, and consist of the intercalation of beds of fossiliferous sand between two masses of boulder clay, the fossils being often of a southern rather than of a northern type. He also refers to the records of borings collected by him and already published, which showed, in several instances, three, four, or even five boulder clays in succession, separated by stratified sands. These interglacial periods are certainly more easily accounted for on Mr. Croll's theory than on any other, as, owing to the numerous terms on which it depends, the eccentricity of the earth's orbit is liable to rapid changes. Many of the instances, however, of interstratified fossiliferous sands seem too insignificant to require so vast an apparatus as a cosmical cause to account for them; rather are they evidences of the dependence of temperature on the atmosphere, whose changes are much more comparable to those of limited beds. Another set of facts adduced by Mr. Croll in illustration of his theory is the evidences we have of glacial conditions in former geological periods, of which he gives a very useful summary, though it seems to us he goes too far in taking proofs of a *warm* climate to indicate glacial epochs preceding and succeeding it, on the ground that all warm periods *must* be interglacial—this is *lucus à non lucendo* truly. Indeed, the warmth of North Greenland in the Miocene period seems to us one of those facts which are not satisfactorily accounted for by the theory—for the eccentricity has seldom been much less than now—and our northern winters are in perihelion.

He thinks he can identify the glacial period proper, and those of the Eocene and Miocene periods, with portions of past time when the eccentricity has been great and yet rapidly changing to small; and attempts thus to get a measure of the length of a geological period, and hence with the aid of other theories and supposed measurements to arrive at the total length of past geological time. These speculations may be ingenious, but they can give no assistance to the solution of a problem of which we really have not yet the data. The title of the book leads us to believe that all the discussion about the glacial epoch is engaged in only to lead up to this, but we must regard that as a much more manageable and therefore interesting problem, and turn now to examine the other theories that have been broached to account for it.

The theory of the sun being a variable star is not in such an advanced state as to warrant a complete discussion from this point of view, and we have seen that mere absence of heat can never cover the land with snow and ice, and this theory therefore may be dismissed.

The only remaining one is that which accounts for it by increased obliquity of the ecliptic. This theory, which has recently been broached in different forms by Lieut.-Col. Drayson and Mr. Thomas Belt, has been espoused by Mr. Woodward in his address to the Geologists' Association, whose paper has been deemed worthy of insertion in the "Arctic Manual." Col. Drayson's form of it, which imagines that the whole mass of ice was formed every winter and melted every summer, may be dismissed as absurd. Not so Mr. Belt's. There can be no doubt that an

increase in the obliquity of the ecliptic would cause a greater difference in the seasons, and this difference we have seen to be the very basis of Mr. Croll's own theory; the results must be the same (and they are rightly seen by Mr. Belt), whatever may be the *cause* of the difference between summer and winter temperature. If this theory were the true one, it is plain that both hemispheres were glaciated at the same time, so that both theories cannot be true; but the matter of fact as to the synchronism or otherwise of the glaciation of two hemispheres can never in the nature of things be determined. But we have still left the question, Has there been or can there be any great change in the obliquity? Astronomers say no. Mr. Belt, however, thinks that the distribution of sea and land and similar causes *may* make it possible for greater changes to occur—a gratuitous supposition that Mr. Croll shows to be groundless. This cause, then, though it may have the general effect of lowering the temperature of temperate and Arctic regions, is not sufficient to cause a glacial epoch.

On the whole, then, there appear to be several independent cosmical causes which affect climate in a greater or less degree, and the probable truth is that a glacial epoch occurs when they all conspire to bring about the same result.

So far, by going from chapter to chapter, we have endeavoured to bring Mr. Croll's arguments into something like logical order. The remainder of the book scarcely admits of this; indeed, we think the author might well have bestowed more care in arranging his matter if it was intended to form a consecutive whole; as it stands, there is much that can only be called a miscellaneous collection of essays without any obvious connection. Among these are his accounts of observations on the North of England ice-sheet, and his speculations as to the direction of its motion. There are also two theoretical questions of great interest discussed—"The physical cause of the submergence and emergence of the land during the glacial epoch," and "The physical cause of the motion of glaciers." With regard to the first of these questions, there are undoubted proofs that great oscillations of the relative level of land and sea have taken place in recent geological times, and the question arises, Was it the land which sank and rose, or the sea which changed its level? It was rightly considered one of the grand discoveries of geology when it was first taught that the changeable sea was that which retained its constant level, and that the "eternal hills" had been but as yesterday beneath the waters; and this principle is not likely to pass away. By it all alterations of level have been ascribed to the motion of the land, and none to the rising of the sea. While agreeing, however, to the principle, we may doubt its universality, and may be prepared to entertain the question whether causes of limited extent may not operate to raise the level of the sea, and thus enable us to account more naturally for such rapid changes as are sometimes indicated. There can be no question but that any considerable amount of water which by the fact of freezing should be retained in either polar region, and form an ice-cap there, would correspondingly shift the earth's centre of gravity and draw the remaining water more over to the side on which the ice-cap lay; and the amount of elevation of sea-level might easily be calculated for any latitude, if we knew the extent of the cap and its manner of deposition, *i.e.* its shape; and the amount would be doubled if the ice-cap were first on one hemisphere and then transferred to the other. This calculation Mr. Croll attempts to make on the very ingenious method of approximation that supposes the ice-cap such as shall make the earth with the cap on one side a perfect sphere. The question can be worked out more directly, as has indeed been done, though with varying results, the mean of which indicates that the rise at one pole due to this cause would be about one-fifteenth of the thickness of the ice melted off the other. If, therefore, we want to account for an alteration of level of 500 feet in England, corresponding to about 600 feet at the pole, we should require to have somewhat less than two miles' thickness of ice on the antarctic regions now. While these figures represent data too far removed from the truth to be at all reliable, and there are, moreover, other causes that may affect the result, they serve to show the kind of thickness required—that it is not *twenty* miles, for instance. Are we prepared, then, to admit that there may be two or three miles of ice on the south pole? This does not appear to us at all an extravagant assumption, when icebergs have been met with 700 or 800 feet out of water, and which must therefore have been considerably more than a mile in total height. We do not think it therefore unreasonable to suppose that during the glacial epoch, or indeed at other times, when there was less ice at the south pole than now, the sea in our latitudes may have stood at a higher level, and that many of the elevated marine deposits and raised sea beaches are due to this cause, and not to depression of the land; for the latter we have no other evidence, and it would involve such vast changes in so recent times that we can scarcely believe would leave all the main valleys and hills as they were before the glacial epoch, and afford no evidences of post-glacial faults. This argument of course does not deny that there *have* been land oscillations during the period, but only that they are not the only ones.

This leads us to the last of the theoretical questions discussed by the author of this work—the physical cause of the motion of glaciers, the answer to which appears to depend upon what is the amount of the shearing force of ice. The remarks which Mr. Croll makes on the theory and experiments of Canon Moseley are very forcible. There is no doubt that the element of time enters largely into the amount of force required to shear ice, and that during this time heat is acting on the ice also, and consequently that satisfactory experiments can only be made on a glacier itself; and also that the theory of the dependence of glacier motion on *change* of temperature will not account for the greater descent in summer than in winter. But what is Mr. Croll's own theory? He, like Canon Moseley, calls in the agency of heat, and indeed, since heat obviously makes a difference in the amount of motion, we have only to find out *how* it makes this difference to determine the cause of the whole motion. He considers the motion of a glacier molecular, that the heat entering at one end melts the first molecule, which then descends by its weight and leaves room for the molecule above it to descend, when *it* melts. This may look very pretty at first sight, but the first molecule would never descend and *leave a vacuum behind it;* so the second

molecule must melt at the same instant, and so on to the other end of the glacier, which is absurd; and besides, what is there in this theory to distinguish a glacier from a common piece of ice? which on this principle ought to flatten out and not retain its shape as it does. Why also are we to suppose the molecule alternately to melt and crystallise when the heat is continuous? The mistake on which this explanation is founded seems to be the confounding of radiation with conduction. It is radiant heat that passes through ice, which is a very bad conductor. Ice at 32° F., heated by conduction, would certainly melt on the outside; the interior can only melt by the *absorption* of radiant heat. We cannot either understand the statement "that ice at 32° cannot take on energy from a heated body without melting," unless it is the exact equivalent of what we have just said; but then no heat could be transmitted, as it would be consumed in melting the ice, and if it were otherwise, still any amount of heat short of the latent heat of water might be "taken on" by a molecule without melting it.

We fear, then, that the complete account of the descent of a glacier is still a desideratum. The various theories may contain elements of truth, but none are entirely satisfactory.

As far as definite results are concerned, it will appear that Mr. Croll's book does not do all he hopes it may, yet we welcome heartily his attempts at reducing complex questions to arithmetical issues, for we thereby gain clearer ideas as to whereabouts the truth may lie, and certainly have the questions put before us in a more definite form. The vast problems with which he deals, and for the suggestion and discussion of which science is so largely indebted to him, are waiting for solution, and every attempt is valuable, both as showing us where to look and where *not* to look for help.

J. F. B.

SPRAGUE'S ELECTRICITY

Electricity; its Theory, Sources, and Applications. By John T. Sprague. (London: E. and F. N. Spon, 1875.)

THE author tells us in his preface that this book is "written chiefly for that large and increasing class of thinking people who find pleasure in the study of science, and seek to obtain a full and accurate scientific knowledge for its own sake, or as part of the necessary mental preparation for many of the departments of modern life." Our examination of the book itself would lead us to an opposite conclusion. We very much question whether any one of the class to whom the author refers will ever have the patience to read through this volume. Certainly they will have but sorry pleasure and anything but full and accurate information. The book abounds in foolish conceits advanced with a show of knowledge that cannot but repel every intelligent reader.

That we are justified in these strictures will be seen from one or two quotations. Here, for example, are some statements taken from chapter ii. in this book. At the outset the author asserts that the fundamental facts relating to frictional electricity given in "one of our standard electrical works (and it is just what all say) . . . are received as absolute truth by electricians . . . and yet there is scarcely a truth in them which is not overweighted by an error, and the simplest facts even are erroneously stated" (p. 17). Mr. Sprague, so far as we are aware, has never done anything to prove that he is able to sit in judgment on the intellectual giants among modern men of science. Mere off-hand condemnation of the laborious work of men like Sir W. Thomson and Prof. Clerk-Maxwell cannot for one moment be tolerated. Mr. Sprague seems to us to be like a child trying to turn one of the pyramids of Egypt upside down because he imagines it has been built the wrong way up. The best teaching is to let him try. This is how the author proceeds in his bold attempt. It is not true, he states, that bodies similarly electrified repel each other; "the repulsion is only apparent; the real cause of the motion is to be found in the attraction exerted by surrounding bodies" (p. 19). And with regard to the electrophorus, "that the dish forms the conductor from the dielectric to the earth, as all electrical books tell us, is an error which will come up for examination by and by" (p. 15).

According to Mr. Sprague the common explanation of induction is all wrong; "the real explanation is" given by him (p. 49). The rubber of an electric machine "is seldom made upon true principles" (p. 33); and as for the earth-connection to an electric machine, we are assured that it is merely imaginary; what we must do is to lead a chain to the floor or gas-pipe, and "hence the idea that we make a connection with the mass or surface of the earth" (p. 29). And further on (p. 40) we read—still concerning the machine—that "because both the poles are insulated and the circuits limited, we are freed from the *ignis fatuus* of the earth-connection." We presume the author does not mean the earth-connection is an *ignis fatuus*, but that the usual explanation is such; it is evidently so to him, for it has landed Mr. Sprague in a quagmire of crudities where we will not attempt to follow him. In these early chapters everything is attributed to "polarisation," a word which has for the author a consoling sound like that "blessed word Mesopotamia." We are told that it is for a similar cabalistic reason electricians employ the term "potential." Not understanding the term, and yet finding it necessary to say something about it, this is how the author discusses the subject: "The word [potential] is always used in place of tension or electro-motive force, because there is something full and smooth sounding about it; but the idea which really does belong to it is a pure mathematical abstraction which only highly trained minds can apprehend" (p. 154).

In another part of this book we meet with dark hints upon "Sprague's patent universal galvanometer," an instrument that is to "do for many purposes, without other instruments and without calculations, the work which at present requires the Wheatstone's bridge and expensive resistance coils, as well as many calculations." But, beyond exciting our curiosity, the author declines to go further, and so we cannot give our readers the benefit of this wonderful galvanometer, which combines "Pyscho" and "George Bidder" in one.

Notwithstanding the grave defects that quite spoil the early chapters in this book, it is only just to the author to point out that the latter part of the volume has considerable merit. Much useful practical information is to be

found in the chapters on electro-metallurgy, a subject that is discussed with great detail, too much so, however, for a general treatise. The author has evidently been at no little pains to collect the numerous tables he gives, and in some instances they are the results of his own experiments. There is also a freshness and originality in the treatment of the sections on resistance and electromotive force that make us regret Mr. Sprague did not submit his theoretical views to some scientific friend before sending his work to the press. If the author had confined himself to the practical part of current electricity we should gladly have recommended his book to our readers.

OUR BOOK SHELF

Anales del Museo Publico de Buenos Ayres para dar a conocer los objetos de Historia Natural nuevos o poco conocidos conservados en este establecimento. Por German Burmeister, M.D., vol. ii. (Buenos Ayres and London: Taylor and Francis.)

IN previous numbers of NATURE (vol. iii. p. 282, and vol. vii. p. 240), we have given some account of the important work which the well-known German naturalist, Dr. Burmeister, is now carrying on at Buenos Ayres.

The number of the *Añales* now before us completes the second volume of this remarkable work, and gives us additional proof of the extraordinary richness of the extinct Mammalian Fauna of the Argentine Republic, to which Dr. Burmeister has devoted so much attention. The Monograph of the Glyptodonts, or extinct gigantic fossil Armadillos, which is now brought to a conclusion, is certainly one of the most valuable contributions to palæontological science that has been produced of late years, and deserves the hearty commendation of all naturalists. This is more especially the case when we consider the difficulties under which the work has been carried on—in a new country, where every man *avidus lucri* is striving to advance his own material interests, and science and all that pertains to it are at an utter discount. On one occasion, we have been told, when one of the most perfect of these Glyptodont skeletons came into the market, the authorities of the National Museum were unwilling or unable to raise the necessary funds to secure it, and it would have left the country and been lost to Dr. Burmeister and his Monograph, had not an English friend found the money. Then, again, the necessity of having the plates lithographed in Europe must add greatly to the difficulties of the undertaking. Under these circumstances we may fairly congratulate Dr. Burmeister and science on the occasion of the second volume of the Annals of the Public Museum of Buenos Ayres having been brought to a successful conclusion.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Peculiarities of Stopped Pipes, Humming-tops, and other Varieties of Organ-pipes

THE peculiarities of a stopped organ-pipe as compared with an open organ-pipe are many and suggestive, and are of the utmost importance to the investigator both to know and to interpret. Without entering deeply into the principles of the craft of organ-building, there are certain matters of fact very necessary to be known before the full bearing of a theory can be estimated or its consistency be judged with true understanding.

By far the greater portion of an organ consists of pipes of the structure called "flue-pipes," or, as here named, "air-reed" pipes, and these are of two classes, the open and the stopped; also they are of two kinds, wood and metal. We have to notice how differently these two kinds are constructed to attain the same ends. In the metal pipe every part is to all appearance immoveable. In the wooden pipe the under-lip, or technically the "cap," is the only adjustable part, and is fixed in position by two or more screws. Within the mouth there is a platform filling the space beyond the windway; it is called the "languid," and it is by varying relatively the level of the edge of the cap to the edge of the languid that the direction of the stream of air is determined; if the cap is set low the angle of flow outward is increased, contrariwise it is lessened, and the art of the voicer decides to the finest degree what is requisite for the quality and speech of each particular pipe. If the wind is much thrown outwards, the speech is slow; if more inward, the speech is quickened; if too much inward, the octave sounds instead of the ground-tone; if too much outward or inward, the pipe will not speak at all. One more power of adjustment remains—the width of the narrow slit through which the wind issues is capable of being varied by alteration of the inner surface of the cap; a wide windway gives a stiffer air-reed, a fine windway gives a thinner one. In a metal pipe we have precisely the same capability of variation, only that we effect our purpose by pressure; the languid is moved higher or lower, not the cap. By means of a rod introduced at the foot or at the top of the pipe, we tap or press the languid into the desired relation to the edge of the underlip. We can also press the upper lip forward or backward; we can, by a like process, reduce the windway or enlarge it as easily. Very simple, yet very beautiful, compensations. In the variations of construction, nothing is done without purpose, nor can you make any one of these minute changes without causing at the same time a flattening or sharpening of the pitch, or a diversity in intonation or quality.

The above details all tend to one point, which I wish to press upon your attention; one distinctive feature belongs to the stopped pipe: the languid is lower than in an open pipe, else the pipe does not attain its proper speech. Consider it well, for it is a fact full of meaning. A necessity of an opposite kind exists in the nature of an open pipe; its demand is that the current shall have determination more to an outward flow. The cause of so essential a distinction between the two classes of pipes will be explained in another paper.

Stopped pipes when they are deep-toned are called "Bourdons," the name the French give to the Humble Bee for its "drowsy hum." Our plaything, "the humming-top," is a true bourdon, is a revolving organ-pipe, has a vibrating air-reed, its principle of action is "suction by velocity," the abstraction of air particles by velocity of *rotation* causing a partial vacuum just as in the stationary organ-pipe by velocity of *passage* of a current of wind.

Bearing in mind the working power of the air-reed, we are brought to consider the effects of the dimensions of the pipe and consequently of the form as well as the extent of the air-column whereon this power is impelled to act, and it is necessary to recur in passing to the question of length. Scientific writers affirm that the length of an organ-pipe for a given note corresponds to the length of the wave in air with an absolute relation, thus expressed. Prof. Tyndall says: "The length of a stopped pipe is one-fourth that of the sonorous wave which it produces, whilst the length of an open pipe is one-half that of the sonorous wave." Prof. Balfour Stewart says, in his "Elementary Lessons in Physics": "In an organ-pipe of this kind, the upper end closed, the primary note is that of which the wave length is twice the length of the pipe . . . the wave length of the sound produced by an open pipe is equal to the length of the pipe, so that it is only half of that produced by a shut pipe of the same length." (One is curious to know why there is this difference of statement from two leading teachers of men; perplexing to the student in want of a leader). Prof. Tyndall demonstrates his affirmation, showing that a stopped tube resounds to the note mid C of 256 vibrations per second; the wave length in air of this note he states to be fifty-two inches; then in proof he measures the jar or tube, and says, "by measurement with a two-foot rule I find it to be thirteen inches, precisely a fourth of the wave length." He then proceeds to affirm the same of organ-pipes, and proves it by tuning-forks and by sounding the pipes to the same note, and believes he has justified his assertions. His hearers do him that justice, and go home believing also. The proof is, however, altogether illusive. No speaking organ-pipe of that length ever gave the note of that pitch. Let us put the assertion to the test. My object lies beyond the recti-

fication of a philosopher's misapprehension, and is meant to show not only that an organ-pipe behaves itself in a manner different to that with which it is accredited, but also why it does so; to show how important a matter in the nature of its action is this neglected difference, and how wide its bearing on the whole system of musical instruments. Here at my hand is a stopped pipe sounding mid C. I measure it interiorly from languid to stopper; it is eleven inches in length, and has a diameter of one-and-a-half inches. Here is an open pipe, same pitch, same diameter, and its length is twenty-three inches. Observe, our stopped pipe is half an inch less in length than half that of the open pipe; yet again notice, it is longer than that pipe would be if severed at the true nodal distance from the languid. How can we read eleven as precisely thirteen, and twenty-three as twenty-six inches? Under the strange notion that it is no matter if there is a difference, this has been done, and the truth of facts lost sight of or disguised in the convenient phrase, "approximately correct." The phrase assumes that there is a standard claiming nature's allegiance. We want to know, not what is correct, but what is true? Further, remark that if you stop the same open pipe at the top, the note obtained will not be an octave deeper, it will be nearly a tone sharper than that; if you stop the pipe at the centre, the note will not be the same as the open one, it will be considerably flatter; in neither case a good tone, since for its proper sounding in such condition the lip would require to be cut higher, mouth a little narrower, perhaps curved, and languid lowered. Every detail we come upon tells plainly of the working power of the reed affecting variably the results in pitch, and I think the reason for these distinctive sounding lengths will be discerned when we reach the consideration of the question of periods of vibration in pipes as tempered by rests.

The fundamental importance of the recognition that pipes of the same pitch varied between themselves as to lengths, was not perceived, nevertheless a qualifying condition was admitted that pitch was "affected by *depth* of the pipe, that is, its distance from front to back, but *width* does not affect pitch." As regards "depth," in no work within my knowledge does there exist any attempt at a solution of the problem how such a result ensues that depth interferes with pitch. It seems to be taken account of only as a disturber of the harmony of things, yet see how significant it is under the new theory of the working abstracting reed. The actual law operating admits of most precise statement when this generating power is acknowledged, viz., the difference of pitch in pipes of varied diameter (other things being equal) is proportional to the difference existing between the area of the cross-section of the pipe and the area of the mouth; the difference in pitch is greatest when the depth from front to back is greatest. It should be observed that increase of depth always flattens pitch, and tends to deprive the pipe of harmonic force. As regards the further assertion that "width" is without effect on pitch, this also is inexact and misses the very point which should have led to closer investigation. It is not true, because the same amount of wind acting over a wider area cannot do the larger extent of work with the same energy. The pitch of every pipe is affected by the width of mouth *relatively*, that is to say, its proportion to the diameter of the pipe. Apart from the ordinary rectangular and cylindrical pipes there are others of so-called "irregular shapes," which are usually viewed as monstrosities, out of the pale even of law padded with exceptions; yet these we shall find are the best evidence to us of the uniformity of the principle of action set forth in these papers, and of the consistency of a theory which recognises no exceptions.

Cylindrical pipes, notwithstanding their symmetry, differ greatly among themselves. The law by which flue-pipes differ has never yet been noticed, which is singular, since it is very striking when the pipes are thoughtfully observed, and gave the first clue to the theory of an arëo-plastic reed. A student well read in all that the best text-books in acoustics can teach, coming to the practical study of organ-pipes, and seeing in a grand organ so multitudinous an array of pipes, the unison pipes of the several stops conspicuous for diversities of diameter as well as of length, would naturally expect that here, if anywhere, he would find confirmation of Reynault's law, "The velocity of propagation of a wave of the same intensity in straight lines *is less according as the section of the tube is less.*" No! this small comfort is denied him; he is in a world of contrarieties; the law is abrogated; he will find the organ world *de facto* governed on principles the exact opposite, "*The velocity is greater as the section is less.*" Investigating further, he will find that, although in length the octaves of particular flue-stops, examined are each very closely upon half the length of the other, yet their diameters do not follow a similar rule, for instead of octave or double octave being in that ratio, he must from the pitch note count to the seventeenth pipe before he will arrive at a pipe half its diameter. For other seeming anomalies, let him proceed to the stops called bassoon, trumpet, and tuba, and he will find that here increase of diameter demands not less length, but greatly increased length, to accompany increase of scale. Books of latest authorities will tell him that in an organ-pipe with a metallic reed "the note produced depends upon the length of the pipe rather than upon the length of the reed. In fact, when the note is established the reed obeys the impulses it receives from the air in the tube. Its use is accordingly rather to economise air and to give certainty and percussion to the striking of the note." Alas, it is inference by theory without test. Remove the whole of the eight or nine feet of the tube, leaving but the few inches of cup or socket, and you will have altered the pitch not more than a semitone.

All organ-pipes having metallic reeds act in conformity with Regnault's law, and the same holds good of wind instruments—trumpets, bassoons, and the like. All organ-pipes possessing air-reeds, flutes also, and some whistles, not all, display an opposite law. The musical tones of all in both these systems are the result of "suction by velocity," and the distinction is that in the former the intermittence is produced by suction under a *propulsive current*, and in the latter by suction under an *abstracting current.* The fact announces the law and leads to its explanation.

HERMANN SMITH

Faults and the Features of the Earth

MY attention has been drawn to an article in NATURE, vol. xii. p. 93, on an exploring party of the Geological Class of the University of Edinburgh to trace out a long fault in Scotland. In this it is stated that particular attention was devoted by the party to the connection between dislocations and valleys, and they came to the conclusion that not a single main valley ran along the fault they were tracing out. As an advocate of the theory *that faults or other breaks greatly induced the present features of the earth*, perhaps you may allow me to say a few words on the subject.

Fault-rock may be friable or hard; the first is inclined to induce valleys, the second peaks or ridges. Faults are of different ages, and therefore the features due to them are liable to be obliterated. Pre-Silurian features may be obliterated by the subsequent deposition of Silurian rocks, and so on upwards until we find many preglacial features obliterated by the glacial drift. In Ireland and Scotland we find more faults in the metamorphic rocks than in the overlying Silurians, in the Silurians than in the overlying Carboniferous and Old Red Sandstone, and in the Carboniferous than in the drift, while each newer accumulation obliterated, or perhaps, more properly, obscured the features in the older.

The fault examined by this party, from the brief description, seems, first, to have had a hard fault-rock, and second, its age to have been far from recent. Consequently, by the first, if the fault induced any features at all in the present surface, they ought to have been peaks or a ridge like that formed by the great Slieve-muck fault in Tipperary, Ireland; while if the second is correct, this fault ought not to form surface features, as any features due to the original fault were long since obliterated; also, the fault has been cut up and displaced by the more recent movements. If a valley chances to run along the line of an ancient fault, it probably was not induced by that fault, but by a much more recent break that for a greater or less distance coincided with the line of the older fault.

Wexford, June 18

Salaries in the British Museum

AMONG your notes of last week is a favourable announcement of my promotion as an assistant in the Geological Department of the British Museum; but whilst thanking you, allow me to point out that it contains a grave misstatement as to the amount of remuneration I receive for my services (as a reference to the Parliamentary Returns will demonstrate); a misstatement alike unjust to the trustees and to myself.

May I venture to ask you to insert this, and so correct the erroneous impression which the paragraph conveys, as to the small amount of the pay received by myself and others in a similar position on the establishment.

British Museum, June 15

WM. DAVIES

OUR ASTRONOMICAL COLUMN

THE DOUBLE STAR Σ 2120.—In the notes to the last catalogue of measures of double stars of the late Rev. W. R. Dawes, he remarks with reference to Σ 2120, or, as it has been frequently called, Herculis 210 (Bode): "This object discovered by Struve is undoubtedly a binary system—the position varying in a retrograde sense, and the distance diminishing." Notwithstanding this positive opinion as to physical connection of the components by so high an authority in this department of practical astronomy, an examination of the path of the companion up to the latest published measures of the Baron Dembowski towards the end of 1870, or, it should be stated, through a period of observation fifteen years longer than that upon which the above opinion was expressed, does not support the presumed binary character of the object, but on the contrary, when the apparent fixity of the principal star is considered, shows pretty decidedly that the variation of angle and distance must be owing to proper motion of the smaller one. In fact we may represent the measures, from Struve's earliest in 1829, to Dembowski's in 1870, by the following expressions:—

$$d \sin P = -1''{\cdot}6806 - 0''{\cdot}12044\,(t - 1850{\cdot}0)$$
$$d \cos P = +1{\cdot}7259 - 0{\cdot}10250\,(t - 1850{\cdot}0)$$

which formulæ imply a secular proper motion of the small star amounting to $14''{\cdot}75$ in the direction $226^\circ{\cdot}0$; they may doubtless be somewhat improved by complete discussion of all the measures, and perhaps some one of the astronomical readers of NATURE may be able to say how measures in the present year are represented.

D'Agelet, Bessel, and Struve have meridionally observed this star.

THE "MIRK-MONDAY" ECLIPSE, 1652, APRIL 7–8.—The following elements of this long-remembered eclipse are founded upon the same system of calculation which furnished so satisfactory an agreement between computation and observation in the eclipse of 1715, lately detailed in NATURE:—

Conjunction in R.A. April 7, at 23h. 4m. 33s. G.M.T.

	°	′	″	
R.A.	17	42	14	
Moon's hourly motion in R.A.		33	0	
Sun's ,, ,, ...		2	18	
Moon's declination	8	24	17	N.
Sun's ,, ...	7	31	40	N.
Moon's hourly motion in Decl.		17	5	N.
Sun's ,, ,, ...		0	56	N.
Moon's horizontal parallax		60	16	
Sun's ,, ...			9	
Moon's true semidiameter		16	25	
Sun's ,, ...		15	57	

The sidereal time at mean noon April 8 was 1h. 9m. 20s., and the equation of time 1m. 38s. subtractive from mean time. The middle of general eclipse April 7, at 22h. 21m. 30s.

Hence the following points upon the central line in its track over the north of Ireland and Scotland:—

	° ′		° ′			° ′		° ′	
Long.	8 25	W., Lat.	50 21	N.	Long.	4 8	W., Lat.	55 3	N.
,,	7 50		51 0		,,	2 47	,,	56 28	
,,	6 3		53 0		,,	1 20	,,	57 54	
,,	5 26		53 42						

At Carrickfergus, where Dr. Wyberd observed the eclipse as described in the "Philosophical Transactions," totality began at 22h. 8m. 34s. according to the above elements, and continued only forty-four seconds. At Edinburgh it commenced at 22h. 22m. 55s., the duration being 2m. 47s. with the sun at an altitude of 39°; and at Arbroath at 22h. 26m. 23s. with the same duration, these being local mean times. Probably there may be other accounts of this eclipse in existence than those commonly quoted when "Mirk Monanday" is referred to.

DIAMETERS OF THE PLANETS.—We give the following values of the apparent diameters of planets reduced to the mean distance of the earth from the sun and of their true diameters in English miles, as being perhaps as reliable as any that can be assigned from existing data. They are founded in every case upon the measures which from observational circumstances appear to deserve the greatest weight, and in the reduction to true values the solar parallax is taken $8''{\cdot}875$, and Clarke's diameter of the earth's equator is adopted. It would of course be idle to attempt to offer final numbers, where the difficulties attending observations and the differences between the results of the most experienced and favourably-circumstanced observers are so considerable.

	″	Miles.	
Mercury	6·35 ...	2,850	
Venus	16·95 ...	7,550	
Mars	9·305 ...	4,150	
Jupiter, Equat....	197·47 ...	88,200	Compression $\frac{1}{15{\cdot}54}$
,, Polar ...	184·76 ...	82,500	
Saturn, Equat....	166·82 ...	74,500	Compression $\frac{1}{9{\cdot}10}$
,, Polar ...	148·50 ...	66,300	
Uranus	68·57 ...	30,600	
Neptune	67·26 ...	30,050	

In fixing upon the apparent diameters of the bright planets it has been desired to adopt values which shall represent the actual arc values that are presented by the true diameters at the earth's mean distance. Many observations would assign larger values, but undoubtedly less trustworthy for computing real dimensions. As is well known, preference in such case is to be given to double-image over wire-micrometer measures, yet even if we confine ourselves to the former mode of observation we by no means secure great consistency of results.

SOLAR HEAT AND SUN-SPOTS

THAT the rainfall of certain parts of the earth tends to vary periodically with the sun-spots has been shown with considerable probability by Messrs. Meldrum and Lockyer, and Prof. Köppen * has detected a similar tendency in the temperature of the atmosphere, most distinctly shown (as might have been anticipated) at stations in the tropical zone. † These discoveries indicate that there is at least some ground for the truth of Sir W. Herschel's surmise, that the heat emitted by the sun undergoes a periodical increase and decrease, concurrently with the varying disturbance of the solar atmosphere, as evidenced by the number of spots and prominences on his surface. But except Mr. Joseph Baxendell, who has published two papers on the subject in the fourth volume of the Transactions of the Literary and Philosophical Society of Manchester (new series), I am not aware that anyone has attempted to investigate the more direct evidence afforded by observations of the black-bulb thermometer.

Mr. Baxendell's work was based on the observations of the Radcliffe Observatory at Oxford, and a series made at Eccles by Mr. Mackereth; the two series extending over the years 1859-66. He did not attempt to institute a direct comparison of the recorded radiation temperatures with the number of the sun's spots, a proceeding which would probably have failed to lead to any definite result in English latitudes and in so cloudy a climate; but took as the first term of his comparison the ratio existing between the excess of the maximum radiation over the maximum air-temperature in the shade, and that of the mean air-temperature over that of the wet bulb, or the dew point deduced therefrom. His conclusion was to the effect that the sun's heat undergoes a distinct periodical variation, coinciding with and directly as that of the spots.

* Zeitschrift der Oesterr. Gesellschaft für Meteorologie. Vol. viii. Nos. 16 and 17.

† It is to be noticed as a remarkable fact that Prof. Köppen finds the epochs of maximum and minimum temperature to correspond (not as might be expected from the results of the present investigation with the maxima and minima of sun-spots respectively), but approximately with the opposite phases; the *maximum* of temperature (in the tropics) preceding the *minimum* of the sun-spots by 0·9 of a year, and the minimum of the former the maximum of the latter by 0·1 year.

It is evident that India offers far greater advantages for investigating the variations of the solar heat than any European country can do, and as observations of the black-bulb thermometer *in vacuo* have now been registered at several stations during the last six or seven years, I have lately examined a portion of these, to see if they afford any direct evidence of a periodical graduated variation in the intensity of the radiation. The result is to me very striking, and if not absolutely conclusive as to the direct variation of the sun's heat with the number of the spots and prominences, certainly, as far as it goes, strongly confirms Mr. Baxendell's conclusions, drawn from indirect evidence.

It is unfortunate that owing to the fragility of the instruments employed and the necessity of exposing them freely, they are very frequently broken; and, as a consequence, the longest series of observations made with one and the same instrument extends over only five years. This is at Silchar in Eastern Bengal. The place is situated in lat. 25°, therefore beyond the tropic; and the climate being very damp and more cloudy than most parts of Bengal, it is not, perhaps, so favourably circumstanced for the present purpose as some other stations.

The means of the maximum sun-temperatures registered on clear days (that is, on days when the proportion of clear sky estimated at 10 A.M. and 4 P.M. did not average less than three-fifths) are given in the following table. The months of the S.W. monsoon are omitted, since in some cases they do not furnish a single clear day according to the above definition, and as a rule such days are too rare to contribute much evidence of value. I give for each month the number of clear days that have contributed to the mean.

TABLE I.—*Average maximum temperature of solar radiation on clear days at Silchar.*

	Days.	1870	Days.	1871	Days.	1872	Days.	1873	Days.	1874

Did this table stand alone, the evidence of any periodical variation would be very doubtful. But we shall presently see that the irregularities that it exhibits are all but completely neutralised by the registers of other stations. It is easy to suggest their explanation, grounded on the fact to which all the registers testify, that the highest sun-temperatures occur, not on days registered as cloudless, but on those on which there is a considerable proportion of cloud, and frequently rain. Such days were numerous in 1874; while in 1871 (the year of sun-spot maximum) days without visible cloud predominated. Leaving the discussion of this question, however, as unnecessary in this place, I will give the combined results of Silchar and eight other Observatories variously situated, some in, and others beyond the tropical zone. These are:—

Port Blair, in the Andamans	lat. 11° 41′	N.
Cuttack, in Orissa	„ 20 29	„
Chittagong, on the Arakan coast	„ 21 39	„
Jessore, on the Gangetic delta ...	„ 23 9	„
Dacca, also on the delta	„ 23 43	„
Hazaribagh,* elev. 2,000 ft. in Western Bengal	„ 24 0	„
Berhampore,* on the Gangetic delta ...	„ 24 6	„
Roorkee, elev. 900 ft. in the N.W. Prov.	„ 29 52	„

Since the radiation-thermometers originally in use at most of these stations have been broken and replaced by other instruments, and since these thermometers (furnished by the best London makers) sometimes differ to the extent of many degrees when placed under the same conditions of exposure, it would be only misleading to compare together the registers of different years recorded with different instruments at the same station. In order to avoid this source of error, and at the same time to bring in evidence as much as possible of the registers, I have taken for each station separately the difference (rise or fall indicated respectively by + and −) of each pair of homonymous months in consecutive years, omitting all cases in which the instrument has been changed in the interval; and then the mean of all the differences thus obtained for the same pair of months. The results are given in the following table, additional columns being added to show how many stations have contributed to the mean of each pair of months. As in Table I., the mean temperatures compared are those of clear days only; but with the exception of Port Blair, I have admitted as clear days those only on which at least four-fifths of the sky on an average was estimated as unclouded at 10 A.M. and 4 P.M. In the case of Port Blair it was necessary to admit days with only one half of unclouded sky.*

TABLE II.—*Annual variation of mean maximum readings of black-bulb thermometers on clear days.*

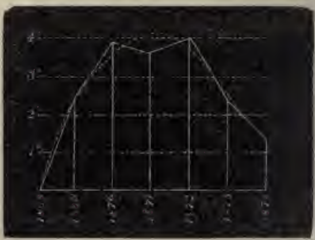
If these differences be plotted as the increments of a series of ordinates, and the curve thus marked out be corrected for its small irregularities *liberâ manu*, its resemblance in general character to the sun-spot curve will be distinctly apparent. (See figure.)



I have been unable to ascertain (here in Calcutta) the number of spots observed during the last few years; but this datum can readily be supplied at home.

LECTURES AT THE ZOOLOGICAL GARDENS†

VIII.

Mr. Sclater on the Pheasants.

IN that Birds possess a high temperature of the blood, they agree more with the mammalian than with other vertebrated animals; the balance of anatomical evidence

* The registers of these two stations taken alone give a curve nearly approximating to the resultant of all the stations, but it is of doubtful validity owing to the thermometers having been twice renewed at both stations.

* I have ascertained by direct comparison that any difference thus introduced is inappreciable, the results being treated comparatively, and not for absolute values.

† Continued from p. 130.

is, however, in favour of their more intimate reptilian affinities. They are characterised externally by their covering of feathers, and by the fore limbs being developed to form wings. These wings, though primarily constructed for flight, in some birds perform other functions. In the Penguins they are employed for swimming, in the Ostrich to assist in running, whilst in the Apteryx and the Cassowary their condition is so rudimentary that they can be of no service to their owners. In the Night Parrot and the Weka Rails the wings are very much diminished.

Birds are divided into from seventeen to twenty well-marked groups, of which the Gallinæ, the order which contains the Pheasants, forms one which is more important in an economical point of view than any of the others, as it contains most of the domesticated species of birds, the ducks and pigeons being exceptions. The Game Birds, as the Gallinæ are commonly termed, may be divided into the following seven sections :—1. The *Pteroclidæ*, or Sand Grouse, birds which inhabit Africa and Western Asia. By some naturalists they are grouped with the Pigeons ; they, however, differ from them and agree with the fowls in laying coloured eggs, at the same time that the young ones run about directly they are hatched. There is one species, found in the steppes of Tartary, in which, unlike its allies, the hind toe is absent. In the year 1863 a flock of Sand Grouse spread over all Western Europe. Prof. Newton tell us, in the "Ibis," that not less than seven hundred individuals must have appeared. A few stragglers were seen for a short time afterwards. 2. The *Meleagridæ*, or Turkeys, are unfortunately so called, as they are in their wild state confined to Northern and Central America. Only three wild species are known, the most northern of which is said to be the parent stock of our domesticated form, although some of the evidence is in favour of the latter having sprung from the Mexican species. The Ocellated Turkey, from Honduras, is a particularly handsome bird. 3. The *Numididæ*, or Guinea Fowl, are represented in Guinea by one species. The four or five others are all confined to Africa ; of these, the elegant Vulturine Guinea Fowl, of which several specimens have been presented to the Zoological Gardens by Dr. Kirk, comes from Zanzibar. 4. The *Cracidæ*, or Curassows, are the representatives of the Game Birds in Central and South America. They will not nest in captivity here, perhaps because, as they are arboreal in their habits, it is not possible to give them suitable abodes. They are said to have been first introduced into Europe by the Dutch, from the island of Curassow, in the West Indies. In some species the cock and hen are identical in plumage ; in others very dissimilar. 5. The *Megapodidæ*, or Megapodes, are confined almost entirely to the Australian region. They are nearly allied to the Cracidæ. Their eggs are laid in the middle of a mound composed of earth and grass, where they are left to be hatched. Many eggs are laid, and the young ones are able to fly within twenty-four hours of leaving the egg. Their breeding habits have been well described by Mr. Bartlett, from examples which have laid in the Society's Gardens. By one species the mound constructed is as much as 15 ft. high and 60 ft. in circumference. The habits of one peculiar species, the Maleo of Northern Celebes, have been well described by Mr. Wallace. 6. The *Turnicidæ*, or Hemipodes, much resemble quails. They are mostly African, one species occurring in Andalusia. Their anatomy is somewhat peculiar. 7. The *Phasianidæ*, or Pheasants, are constituted by (*a*) the *Tetraonidæ*, or Grouse, inhabitants of the mountainous regions of Europe and Northern Asia. In all the species the legs, and in some the toes, are feathered. They do badly in captivity. The best known of them are the Prairie Fowl, Capercailzie, Black-cock, and Ptarmigan. (*b*) The *Perdicidæ*, or Partridges, are found in every part of the Old World. The Snow Pheasant of the Himalayas is one of the largest species. The Impeyan Pheasant, from the same locality, is a closely allied form. These birds are represented in America by (*c*) the *Odontophoridæ*, or Colins, sometimes called toothed Partridges, because the bill is slightly toothed. They are much more arboreal than their Old World representatives, and none of them attain a great size. (*d*) The *Phasianidæ*, or Pheasants proper, form about forty species, arranged in seven genera. The story runs that the common Pheasant was first brought from Colchis by the Argonaut, whence its scientific name, *P. colchicus*. The genera include the *Crossoptilons*, or Eared Pheasants of Northern Asia, of which there are four species : the true Pheasant, preserved in this country ; the *Thaumalea*, or Gold Pheasant, with its superb ally, the Amherst Pheasant of Central Asia, first made known from a specimen brought over by the Lady Amherst when returning from an embassy to the King of Ava. Further facts respecting its distribution have been obtained by Dr. John Anderson and Mr. Stone. The *Euplocami*, or Kaleeges, are represented by twelve species. They are intermediate between the Pheasants and the Fowls. A new species has been quite recently obtained by Mr. Gould from the interior of Borneo (*Lobiophasis*). *Gallus* is the name given to the genus which includes the Fowls, of which there are four species. The Jungle Cock of India is the wild ancestor of the domesticated bird ; others are inhabitants of Ceylon and Java. *Ceriornis* includes the Tragopans, which are peculiar in having horned appendages to the head. There are five species in this beautiful group. (*e*) The *Pavonidæ*, or Peafowls, are natives of the forest jungles of India, and such being the case it is strange that they so well resist the winters of our own country. *Polyplectron*, or the Peacock Pheasant, is an allied form ; it is aberrant, however, in that it is monogamous and lays only two eggs. The Argus Pheasant also belongs to the same family.

THE PROGRESS OF THE TELEGRAPH *

VIII.

MORE daring inventors, as we have seen, entered the field—Nott and Gamble, with a letter-showing telegraph ; Edward and Henry Highton, who produced an array of signal apparatus, in some cases evading the Cooke and Wheatstone patents by the use of nickel for the electro-magnet in place of soft iron. But formidable beyond all other competitors was the talented Alexander Bain, the Edinburgh watchmaker, who has contributed largely to the improvement of the telegraph by his singularly beautiful adaptations and chemical printing arrangements. Expensive litigation speedily followed, and the directors in most cases compounded with their opponents. Alexander Bain was made a director of the Company, and at the same time received 12,000*l.* for his chemical printer, and most of the other opposing patents became the property of the Company by special arrangements with the inventors. By means such as these a monopoly for a time was secured, even though it was purchased at an exorbitant price. Monopoly at that time represented commercial gain, and every aspiring inventor was sooner or later run off his feet by the powerful and wealthy corporation. Such is the early history of the introduction and opening of the Electric Telegraph as a means of the transmission of inland intelligence. The telegraphic connection of Great Britain with the Continent of Europe at this time was scarcely developed, the extent of electrical communication by the continental land lines being circumscribed.

This, however, thanks to further applications of science, is no longer the case. The planet is now girt by telegraphs. First, there is the "Great Northern,"

* Continued from p. 113.

stretching from London, the telegraphic centre of the world, by land and submarine circuits into Denmark, Norway, Sweden, and Russia in Europe, thence across the wilds of Siberia in Asiatic Russia to the Japanese Sea, and on to Japan, terminating within the tropics, at Hong Kong. Secondly, the "Eastern Telegraph," which, crossing the Bay of Biscay, reaches Lisbon, and thence threading its way under the dark blue waters of the Mediterranean Sea to Suez, reaches India by the Red Sea and Indian Ocean, and on to Ceylon (Point du Galle), joining the "Great Northern" at Hong Kong *viâ* Singapore. Thus by means of these two great systems a complete circuit of the continents of Europe and Asia is effected, the one within the limits of the tropics, the other bordering upon the Arctic circle, reaching as it does to 62° of north latitude. At Singapore the circuit is divided, a branch extending south to Sumatra, Java, and the continent of Australia,—Sydney, Melbourne, and Adelaide being reached; New Zealand being about to be included. Thirdly, there is the vast stretch of the South Atlantic Ocean traversed by the circuits of the "Brazilian Submarine," connecting Great Britain, *viâ* Lisbon, with Madeira, St. Vincent, and the continent of South America to Pernambuco. There it joins the coast submarine circuits of the "Western and Brazilian," extending north to Para and south to Bahia, Rio Janeiro, Rio Grand do Sul, and Monte Video in the River Plate, at which station, in connection with the local lines of the River Plate Company, it reaches Buenos Ayres, thence by means of the wires of the Argentine Republic, crosses the Andes into Chili and Peru. From Para the electric circuit is extended (Para and Demerara being now under completion), by way of the West India Isles, Jamaica, and Cuba, to Florida, there joining the extensive system of the United States Trunk lines; to San Francisco, west, and Newfoundland, east; and thence, by the circuits of the "Anglo-American" and "Direct United States" cable, crossing the Atlantic Ocean to Great Britain. Thus the New World is also encircled by two great systems, the one almost equatorial, the other within the higher degrees of northern latitude.

In dealing with submarine circuits the electrician has several matters to consider and accurately adjust, some of which will be more fully considered hereafter. First, there is the copper-conducting wire, its capacity according to the length of the circuit. Too small a conducting wire on a circuit of a given length would offer too great a resistance; too large a conducting wire would be equally faulty, induction increasing in greater proportion from its large superficial surface than its increased sectional area augments the speed. The exact sectional area of the wire has therefore to be determined; then for insulation, the best relative proportion in weight, and sectional measurement between the wire and that of the insulating material. Insulation, as is well known, may be obtained by a mere film of a non-conductor surrounding the wire. This is illustrated by the simple experiment of passing a weak voltaic current of electricity through an extended fine metallic wire immersed in a trough of water. Under ordinary circumstances it is but natural to suppose (water being a conductor) that there would be no insulation; not so; by the action of the current through the wire decomposing the water, a fine non-conducting film of hydrogen is developed surrounding the wire, which, with a strength of current adjusted to the resistance of the wire, will separate the water from the metallic conductor, perfect insulation being maintained. Destroy the balance between the current and the wire, and the hydrogen, evolved too rapidly by reason of electrical decomposition, accumulates upon the surface of the wire and, passing off in the form of small bubbles, destroys the insulation. This simple experiment demonstrates that insulation in the abstract sense may be obtained by a very thin covering of a non-conductor. It is, however, in practice mechanically unsafe to rely upon mere tissues of insulating material surrounding the conducting wire; a certain thickness is absolutely necessary for security. Every insulated core to be used for submarine purposes, to ensure integrity of manufacture, should be tested under pressure, so as to break down all mechanical imperfections in the coating of the insulating medium, before the cable is submerged. The determination of the dimensions of the insulator influences also

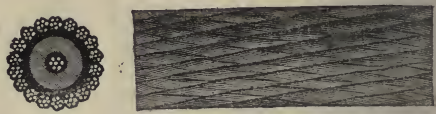

FIG. 34.—First Atlantic Cable, 1857 (natural size).

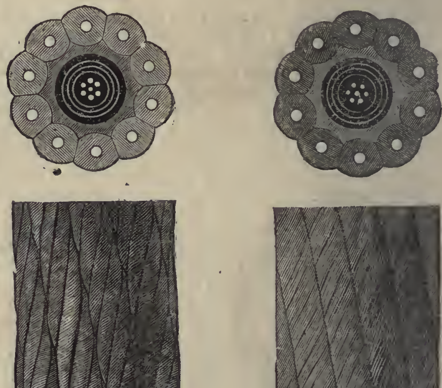
materially the inductive effect of the circuit; and when it is remembered that the best insulating material represents a cost of about 6*s*. per pound weight upon the wire, the close connection between science and pounds shillings and pence becomes at once apparent. The variations in weight per nautical mile of copper and insulation in some of the recent important cables are here given. The Atlantic main cables of 1865 and 1866: copper 300 lbs., insulation 400 lbs.; lengths each about 1,900 nautical miles. French Atlantic main cable, 1869: copper 400 lbs., insulation 400 lbs.; length about 2,600 nautical



1865. 1866.

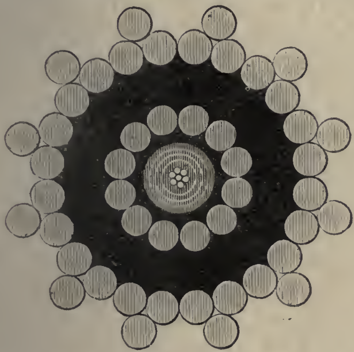
FIG. 35.—Atlantic Cables laid in 1865 and 1866, between Valentia and Newfoundland (natural size), weight per naut. 1·75 tons.

miles. Falmouth and Lisbon, 1870: copper 120 lbs., insulation 175 lbs.; length about 800 nautical miles. Anglo-Danish Cable, 1868: copper 180 lbs., insulation 180 lbs.; length, 365 nautical miles. Hong-Kong—Shanghai, 1870: copper 300 lbs., insulation 200 lbs.; length, 1,100 nautical miles. China Telegraph, 1870: copper 107 lbs., insulation 140 lbs.; length, 1,632 nautical miles. British India Extension, 1870: copper 120 lbs., insulation 175 lbs.; length, 1,448 nautical miles. Eight important submarine circuits have here been summarised, and in six it will be found that the proportions in the weight per nautical mile between the copper and insula-

tion vary in an extreme degree. Thus there is found copper and insulation in the respective proportions by weight of 1 to 1, also 3 to 4, also 3 to 2, also 2 to 3, and also in the irregular proportion of 11 to 14. By these figures it appears that there is no accepted ratio, and every new cable seems to be constructed according to the electrical views of the designer, in some cases at an enormous cost, as compared with others of similar length and equal efficiency in transmitting power. Thus, by reducing the weight of material per nautical mile into an average money value, assuming for copper 1*s.* 2*d.* per lb., and insulation 6*s.* per lb., we obtain the following ratios :—

1,100 nautical miles :	copper	£16 0	insulation	£60
1,632 ,,	,,	6 5	,,	42
2,600 ,,	,,	23 10	,,	70
2,000 ,,	,,	16 0	,,	70

With such indiscriminate specifications there is certainly something left to discover, and the next few years may



Shore end.

Intermediate. Main.

FIG. 36.—French Atlantic Cable laid between Brest and Island of Saint-Pierre, 1869.

determine with some degree of accuracy the true proportions by weight to be adopted between the conducting wire and the external thickness of the insulator, to obtain the best practical results at the least expenditure of capital on a circuit of given length, worked with one of the sensitive recording instruments already brought under notice. As an example of the augmentation of speed upon a submarine circuit, according to the delicacy of the recording instrument employed, upon the Great Northern cable between England and Denmark, 365 nautical miles in length, with the most improved submarine morse, an average of seventeen words per minute was obtained; with the Wheatstone's automatic thirty words, and with the Thompson syphon recorder fifty words per minute are practically reached.

For many years there has existed a divided opinion as to whether a light submarine cable, combining economy of construction with mechanical facilities of laying, is not the right system to adopt as against the heavy and more expensive form of iron covered cable. The light cable theory may be said to be based upon the opinion of the late Lieut. M. F. Maury, who through every opposition adhered in principle to light cables. His argument may be expressed in his own words: "You may snap a taut rope, but you cannot break a slack line." This remark may nautically be quite true, but electrically far from correct, for the following reasons. In submerged cables, speed is greatest upon the shortest line. Now, in deep-sea telegraphy, in the only circuits upon which a light cable could possibly be employed with any security against mechanical interruptions, two or three points come into play. Supposing a light cable were to be used over, say, a circuit of 2,000 miles, with an average depth of 1,500 fathoms, or about $1\frac{3}{4}$ miles. First, take the specific gravity of the light cable as compared with water, at what rate will it sink to the bottom? if not so adjusted as to sink at about one mile per hour (looking to the enormous sweep between the paying out steamer and the bottom of the ocean at the depth of $1\frac{3}{4}$ miles), it is more than probable that although you cannot break a "slack line," it may be so twisted and contorted by surface-currents and under-currents moving at various velocities or even in opposite directions as it slowly sinks to the bottom by reason of low specific gravity, that a very great length of cable may be paid out (as a slack line). Secondly, the cost of this increased mileage must be taken into account as compared with that of the heavier iron-sheathed cable upon which a mechanical strain can be placed to ensure more or less a "Bee" line. Thirdly, the speed of transmission through a submarine cable is inversely as the square of the length. Now, if this is practically correct, it is easy to determine whether the best commercial results will be obtained from a light cable with increased electrical resistance, although it may be carried out at a less original outlay, or from a shorter cable more costly per mile from increased strength and weight of iron, but with greater transmitting speed, and in consequence dividend earning capacity. But of equal importance with any of the previous points is the impossibility of grappling a light cable from any considerable depth in cases of injury affecting the insulation. To raise a cable from a depth of $1\frac{3}{4}$ miles involves a great strain upon the cable, and unless the breaking strain has been calculated to meet such an emergency, any successful attempt at restoration must be abandoned, and the entire line is rendered useless and the capital lost. Every submarine cable should be laid with a certain percentage of slack, regulated according to depth of water and surrounding circumstance. The average slack is from 8 to 14 per cent.

The first Atlantic cable, 1857, between Valentia and Newfoundland, is shown in elevation and section at Fig. 34. This cable, from imperfect construction, remained electrically sound for a very limited period, and very few messages were successfully passed through the conducting wire. It, however, became the pioneer to success, and elucidated several important points in connection with the design of the 1865 and 1866 Atlantic cables shown at Fig. 35. The covering of these cables consists of ten strands of Manilla hemp, each containing a homogeneous steel wire. The French Atlantic iron-sheathed cable between Brest and Saint-Pierre, laid in 1869, is shown at Fig. 36.

(*To be continued.*)

SCIENCE IN GERMANY

(*From a German Correspondent.*)

SINCE Darwin first gave the signal for a complete rupture with the old tradition of the morphology of animals, Germany has zealously continued working in the new direction, trying to bring anatomical, embryological, and biological facts into causal connection with each other by the comparative method. Darwin's theory remains the basis, and it has been principally Haeckel who, in advance of all its supporters, deduced further important consequences; the antagonists of the theory have confined themselves to a purely negative criticism. At one time the whole theory with all its suppositions and deductions was rejected by them; at another, the theory of descent was accepted in principle, but the further representation of its connection with the anatomy and the development history of animals was refuted; in all cases they either returned to the old views openly or they were satisfied with simple contradiction, leaving it to the future to fill up the gaps thus produced in the theory. In a work that has lately been published, the attempt has been made to consider the whole science of the morphology of animals from a different point of view. This work is: "Die Entwicklungsgeschichte der Unke als Grundlage einer vergleichenden Morphologie der Wirbelthiere" (the History of Development of *Bombinator igneus* as the basis of a Comparative Morphology of Vertebrata), by Dr. Alexander Götte, Professor of the University of Strassburg.

From a careful examination of the individual history of the development of Vertebrata and comparative consideration of the lower types, Götte tries to determine the morphological laws for the individual species, and from this to deduce their causal connection; he thus arrives at certain general theorems which, according to his view, form the basis for a conception of the origin of new animal species, totally different from Darwin's view. On the one side Götte does not look upon the animal ovum as a cell, nor in fact as a living organism at all; this of course is different from all other theories hitherto published. According to his view the cells, which are the basis of the formation of the ovum, only produce a conglomeration of a certain material (yolk) in a certain arrangement, but are themselves dissolved sooner or later, so that the complete ovum is a peculiar body, not living, but endowed with properties that enable it to be converted into a living organism under certain conditions. He maintains that this capacity for development is not the simple consequence of the chemical composition of the yolk, but that it only contains the motive force which is freed by chemical processes, and can do very different work according to the physical conditions under which it happens to be. The result may therefore as likely be the destruction of the ovum as its further development. For the latter, perfectly certain conditions of form are necessary, which have already been initiated during the formation of the ovum, and cause the force in question to work in a direction just as determined and certain as they are themselves. The results in that case are self-divisions of the yolk, when the parts are either of equal or of different sizes, and produced at different intervals. The former separate very soon and form separate individuals, which therefore consist only of one element and represent the lowest type (Protozoa); the ova of Matazoa, which are unequally divided according to a certain law, remain whole. Their coarser formation is brought about in a purely mechanical way, each division causing a displacement.

Thus Dr. Götte finds the basis of the fundamental structure, the type of each animal species, in the differences originating through the laws regulating the first divisions of the yolk.

NOTES

AN Exhibition of 50*l.* a year, tenable for four years, was recently devoted by the Endowed Schools Commission for annual competition between the four schools of Taunton, Tiverton, Exeter, and Sherborne. The details of the competition were left entirely to local trustees, whose names we do not know, but whom we understand to be gentlemen of the county of Somerset. The regulations issued by the trustees are before us. They very properly order that the examination shall be conducted by the Oxford and Cambridge Schools Examination Board. The subjects proposed by that Board include four groups, of which Science is one, and all candidates, whether choosing to take up Science or not, are permitted, if they please, to substitute Botany for Latin Verse, and Physical Geography for Greek Prose Composition. The scheme of the Somersetshire trustees includes all the subjects named by the Universities *except those which come under the head of Science*, refusing to permit any branch of science to form part of the examination, whether as an independent topic or as an alternative. We content ourselves for the present with the statement of a fact likely to interest all our readers, those more especially who are aware of the efforts that have been made during the past six years to establish in the county of Somerset a centre of first-rate scientific teaching.

AMONG the additional estimates recently voted by the House of Commons is one for the salary of an Assistant-Director to the Royal Gardens at Kew. Everyone will be rejoiced to hear that the arduous duties of the Director are likely to be lightened by this appointment, which has been filled up by the selection of Prof. Thiselton Dyer.

IN connection with the Commission appointed by the President of the United States to experiment and report upon the metals used in construction (NATURE, vol. xii. p. 94), Mr. R. H. Thurston, the Secretary, has issued circulars expressing his desire to secure the assistance of all who are interested in this great work, and through them to obtain all information available as the result of the labours of earlier or of contemporaneous investigators and observers. The circulars indicate the scope of the labours undertaken by this Commission, and request aid from all in a position to render it, in the collection of all information which may be accessible, relating to either the general work of the Commission or to the special subjects assigned to its committees. Data collected in the course of ordinary business practice, and the records of special researches previously made or now in progress, are particularly desired. It is expected that the Commission will receive valuable information and useful suggestions, both from business men and from men of science, and it is hoped that the work undertaken by the Commission may be supplemented by original investigations made by both these classes. The great importance of this work justifies the expectation of an earnest and effective co-operation. Part of the work of the Commission is the investigation of the methods and effects of Abrasion and Wear of metals in engineering and mechanical operations. Valuable data for the purpose could be furnished by railway engineers and others in regard to the wear of rails, wheels, axles, journals under heavy loads or at high velocities, the wear of tools, and other points, and we hope that all in this country who have it in their power will lend what aid they can to this important Commission. Another part of the Commission's work is a series of determinations of the effects of carbon, phosphorus, silica, manganese, and other elements, upon the strength, toughness, elasticity, and other qualities of iron and steel. Mr. A. L. Holley, Chairman of the Committee on Chemical Research, issues a circular giving detailed instructions as to the specimens and kind of information wanted. We should advise all interested to apply to Mr. R. H. Thurston, Stevens Institute of Technology, Hoboken, N.J., for detailed information; and we think the

Board would do well in sending circulars to the engineers of our principal railways, as well as to all others who are likely to be able to give them help in their laudable and valuable work.

We are informed that H.M.S. *Challenger* will have completed her cruise and be back in this country by April of next year.

The library of Audubon, the ornithologist, was destroyed by fire in April last. It was in the house of Mrs. Bakewell, the sister-in-law of Audubon, at Shelbyville, Ky.

The twenty-fourth annual meeting of the American Association for the Advancement of Learning will be held in Detroit, Mich., beginning on Wednesday, August 11 next, under the presidentship of Mr. J. E. Hilgard, of Washington.

Dr. Horner, the medical officer on board the *Pandora*, which left England yesterday for the Arctic seas, will take upon himself all the meteorological duties of the expedition. Lieut. Banyan, of the Dutch navy, will act as scientific officer, it being intended that botanical and marine research will form a prominent duty of the expedition. Hall's Esquimaux Joe also accompanies the expedition, and altogether there are thirty-two souls on board. Capt. Allen Young hopes to get as far north as Carey Island, at the entrance of Smith's Sound. On this island a "post-office" or cairn has existed for many years, and, accordingly, all the letters Capt. Allen Young takes with him for the *Alert* and *Discovery* will be deposited here, unless he falls in with one of those vessels. The commander of this new expedition will push to the north-west after leaving Carey Island, and if the *Pandora* succeeds in forcing a way through the north-west passage, as Capt. Allen Young hopes, she will be the first steamship to accomplish the marvellous feat. She may possibly return in November next.

In Part X. of the *Deutsche Rundschau* there is an excellent review of Capt. Lawson's wonderful book, "Wanderings in the Interior of New Guinea" (which we noticed in our issue of the 3rd inst., vol. xii. p. 83). The review is by Prof. A. B. Meyer, director of the Zoological Museum at Dresden. Like every sensible man, Prof. Meyer points out the absurdities with which this book is crammed. Indeed, he owns that he was almost of opinion that it was the author's intention to write a satire on modern narratives of travel, and that on the last page of the book the reader would be told of this; "but, unfortunately, Capt. Lawson is constantly in earnest; indeed, he left no stone unturned to make the book attractive, and to pass off its contents as real facts." Prof. Meyer dwells at some length on Capt. Lawson's marvellous mountain ascents, on his wonderful hunting feats, and his most surprising discoveries in the animal and vegetable world. He points out that with regard to the quadruped fauna it is well known that tigers are not found further eastward than Java, monkeys not further than Timor, and deer not further than Halmahera, and that it is incredible that these species, besides buffaloes, foxes, and hares, exist in New Guinea. Prof. Meyer, in conclusion, thinks it rather surprising that shortly after the publication of this wonderful book of fiction a deputation led by the Duke of Manchester should have waited upon the Colonial Secretary with a view to induce the Government to annex New Guinea. He asks, "Was this a consequence of the marvellous description of the distant country, or has the sensation novel been manufactured to order?"

A new steering balloon by Smitter is being exhibited, suspended in the middle of the Alcazar in Paris. The measurement is only 6,000 cubic feet, but the balloon is so light, that when filled with pure hydrogen it must float. A considerable sum of money has been invested in it, and great ability has been displayed in the construction. Although no practicable result in open air may be hoped for, it is a wonderful piece of clockwork. In connection with this subject it is stated that for several months past a firm of engineers have been experimenting privately at the Crystal Palace with an aërial steamer of a novel and promising character, weighing 160 lbs. Experiments are stated to have proved the capability of two vertical screws, each 12 feet diameter, to raise a weight of 120 lbs.; the steam-engine, with water and fuel, forming part of the weight so raised to the extent of 80 lbs. The power exerted by it is equal to two-and-a-half horses. The communication of motion is given by a vertical axis emanating from the car.

At a Congregation held on Friday, the report of the Cambridge Syndicate recommending the purchase by the University of the collection of models, instruments, and tools used by the late Prof. Willis was confirmed.

Capt. R. F. Burton writes to the *Times* stating that the Italian African Expedition, under the Marchese Antinori, is reported to have for its ultimate object the wholly unvisited section to the south-west of Christian Abyssinia and the Abai River, "connecting known countries with the so-called Victoria Nyanza Lake."

We regret to announce the death of M. Le Besgue, oldest Correspondent to the Geometry Section of the Paris Academy of Sciences. He died on June 12, at Bordeaux.

On Tuesday a deputation from the Highland and Agricultural Society of Scotland waited upon the First Commissioner of Works, to ask the Government to proceed with the Survey of Scotland, which had been for some years in abeyance, and also to allow it to be done on a 25-inch scale of maps. A memorial was handed in to show that the opinion of the Scotch people was that the Survey should be at once carried out. Lord Henry Lennox promised to give the subject his best consideration, and remarked that the applications for the same object from different parts of the United Kingdom made it difficult to obtain from the Treasury any grants for the purpose.

An important Report of a Committee of Council appointed to consider the requirements of Oxford University, as amended and adopted by Council, has been circulated for the information of members of Convocation. The "Requirements of the University" may be conveniently divided into Provision for Buildings and Institutions, and Provision for Professors and Teachers. Under the head of Buildings and Institutions, it is stated that with reference to the Botanic Garden, if it is to remain where it is, the lease being renewed, considerable amount of reconstruction is required, estimated at 4,000*l*. If it is to be removed to the Parks, a much larger outlay will be required. With regard to the University Museum, the heads of the three chief departments (Chemistry, Biology, Physics) report that additional buildings are required in each of the three, roughly estimated in all at 30,000*l*. Under the head of Provision for Professors and Teachers, the Committee find many demands which it is difficult to meet at once; one of their principal suggestions is the appointment of a Board for the following purposes:—1. To appoint lecturers from time to time to deliver lectures in the University on any subject that may seem to the Board to claim attention, and to assign payment to such lecturers. 2. To make occasional grants to individuals for the purpose of carrying on special work in connection with the studies or institutions of the University. 3. To appoint Readers for limited periods, not exceeding ten years, in subjects in which public teaching within the University may seem to the Board to be desirable; and to assign the stipends to such Readers; such appointments and the stipends being subject to the approval of Convocation. The

Board also, under certain conditions, might be entrusted with the duty of appointing Professors for life. It appears, however, that several additions to the permanent staff of Professors will be required. These must be provided for, the Report states, from time to time, by statute. Thus, for example, the following suggestions have been made with regard to the chief departments of study pursued in the Museum :—1. In the department of Chemistry it is stated that an additional professorship is required. 2. In the department of Physics also it is stated that an additional professorship is required. 3. In the department of Biology it is proposed—(*a*) That the present Linacre Professorship should become a Professorship of Human Anatomy and Ethnology. (*b*) That the Hope Professorship of Zoology should become a Professorship of Zoology and Comparative Anatomy. (*c*) That the Clinical Professorship of Medicine should become a Professorship of Physiology and Public Health.

A CORRESPONDENT sends us the enclosed cutting from *Le Français* as an illustration of how they do things in France :—"On sait que sur la proposition de M. de Cumont, ministre de l'instruction publique, des cultes et des beaux-arts, l'Assemblée a voté, le 18 juillet dernier, une pension annuelle et viagère de 12,000 fr. à M. Pasteur, membre de l'Institut, professeur à la Faculté des sciences de Paris, à titre de récompense nationale. Un nouveau décret, rendu par M. le maréchal de Mac-Mahon sur le rapport de M. Wallon, contre-signé par M. Leon Say, vient d'accorder une nouvelle pension de 6,000 fr. à M. Pasteur, indépendamment de celle de 12,000 fr. qui lui avait été donnée précédemment. De telles mesures ne peuvent qu'encourager nos hommes de science et stimuler l'esprit de découverte. Cette pension permettra donc d'assurer d'une manière digne de lui les jours d'un homme qui compte près de trente-trois années de services dévoués, et que les fatigues d'un travail assidu ont mis dans l'impossibilité de continuer à exercer ses fonctions de professeur."

LAST Thursday, in the House of Commons, in reply to a question by Sir John Lubbock, the Chancellor of the Exchequer said he would be ready to consult with his colleagues in the course of the autumn to see whether the object of preserving the ancient monuments of the country could in any way be carried out. Sir J. Lubbock, considering this a favourable answer, said he would withdraw his Ancient Monuments Bill.

A SPECIMEN of a sturgeon, eight feet in length, has been added to the Manchester Aquarium. Several examples of the Wolf, or Cat Fish, and three of the Monk, or Angel Fish, each five feet long, are also to be seen in the same building.

DURING this season the *Morning Post* has made a speciality of noticing the proceedings of some of the learned societies. The lectures at the Royal Institution have generally occupied half a column, and some of the popular lectures of the Zoological Society have been given at equal length. In a notice of one of the ladies' lectures of Prof. Bentley at the Botanic Society is this passage :—"Future historians of the social condition of the people of England at our period will have to make constant reference to the daily press, and it is therefore but right, alongside of the notices of the culture of music and the sister fine arts, to record each attempt to spread the knowledge acquired by men of science." We are glad the *Morning Post* has set so good an example.

PROF. NORDENSKJÖLD's expedition left Tromsö for Novaya Zemlya on June 8. The expedition is undertaken on board the Norwegian Arctic sea-yacht *Pröven*, Capt. J. N. Isaksen, who has been to Spitzbergen and Novaya Zemlya a great many times previously. On the southern coast of the latter island the party expect to meet with Samoyedes; they intend then to move in an easterly direction, towards the rivers Obi and Yenesei. Prof. Nordenskjöld will then leave the ship to continue the expedition by boat.

THE so-called tobacco-meal, the *Kölnische Zeitung* says, has been successfully used in agriculture for the destruction of noxious insects, but it has not yet been applied largely on account of its high price, which is caused by heavy import duty. The Prussian Minister for Agriculture has just addressed a letter to the Minister for Commerce with a view to reduce this duty or to take it off entirely. The only obstacle lies in the fact that the meal might be used for the manufacture of snuff. A Hamburg firm is said to have a stock of over thirty tons of this meal.

WE regret to learn that Mr. Alexander Agassiz, director of the Anderson School of Natural History, has been unable to make arrangements for a third session of this establishment during the present summer. He announced some time ago that, in view of the expense of the enterprise and the limited funds at his command, it would be impossible for him to proceed unless a sufficient number of students could be found willing to pay fifty dollars for the course. This appeal not proving effectual, he has given notice that the school will not be opened during 1875.

THE French Minister of Public Instruction has established a new commission to report on the state of meteorology and the improvements to be introduced in the system of observations, as hitherto practised at the Observatories of Paris and Montsouris, and other public establishments.

COL. MONTGOMERIE, the representative at the International Geographical Congress of the Royal Geographical Society and the Indian Survey Office, has arrived in Paris. A representative of the English Admiralty is expected very shortly. It is hoped that the Admiralty will send to Paris one of the magnificent yachts of the English navy for exhibition during the Congress. An immense quantity of goods for exhibition is stated to have already arrived from London.

THE death of Mr. Thomas Baines, the African traveller, is announced.

AT the last meeting of the Edinburgh Botanical Society, the *British Medical Journal* states, Dr. T. A. G. Balfour reported some interesting experiments on the *Dionœa muscipula*, which he considered a carnivorous plant. He showed that the irritability under which the leaf contracts is resident in six delicate hairs, so placed on the surface of the leaf that no insect could avoid touching them in crawling over. Chloroform dropped on a hair caused the leaf to close immediately; water had no such effect. Contraction only lasted for a considerable time when any object capable of affording nutrition was seized, when it lasted for about three weeks, and the interior of the leaf gave out a viscous acid secretion. A number of interesting points were made out with regard to the secretion, digestion, and absorption performed by the plant.

THE additions to the Zoological Society's Gardens during the past week include two Dorsal Squirrels (*Sciurus dorsalis*) from West Mexico, presented by Mr. John G. Haggard; a Yellow-shouldered Amazon (*Chrysotis ochroptera*) from South America, presented by Miss Amelia Grove Grady; a Grison (*Galictis vittata*) from South America, a Hobby (*Hypotriorchis subbuteo*), European, a Humboldt's Lagothrix (*Lagothrix humboldti*) from the Upper Amazon, purchased; ten Summer Ducks (*Aix sponsa*), seven Spotted-billed Ducks (*Anas pœcilorhyncha*), four Temminck's Tragopans (*Ceriornis temminckii*) bred in the Gardens.

RECENT PROGRESS IN OUR KNOWLEDGE OF THE CILIATE INFUSORIA *

II.

THE reproductive process was lately followed by myself through some of its stages in a very beautiful Vorticellidan obtained abundantly from a pond in Brittany.† The zooids which form the colonies in this Infusorium are grouped in spherical clusters on the extremities of the branches. They present near the oral end a large and very obvious contractile vesicle, and have a long cylindrical nucleus curved in the form of a horseshoe.

In the internal protoplasm are also imbedded scattered green chlorophylloid granules. No trace of the so-called nucleolus was present in any of the specimens examined.

Among the ordinary zooids there were usually some which had become encysted in a very remarkable way, and without any previous conjugation having been noticed. These encysted forms were much larger than the others and had assumed a nearly spherical shape; the peristome and cilia-disc had become entirely withdrawn, the contractile vesicle was still obvious, but had ceased to manifest contractions; brownish spherical corpuscles with granular contents, probably the more or less altered chlorophylloid granules of the unencysted zooid, were scattered through the parenchyma, and the nucleus was not only distinct, but had increased considerably in length. Round the whole a clear gelatinous envelope had become excreted.

In a later stage there was formed between the gelatinous envelope and the cortical layer of the body a strong, dark-brown, apparently chitinous case, the surface of which in stages still further advanced had become ornamented by very regular hexagonal spaces with slightly elevated edges. In this state the chitinous envelope was so opaque that no view could be obtained through it of the included structures, and in order to arrive at any knowledge of these it was necessary to rupture it. The nucleus thus liberated was found to have still further increased in length, and to have become wound into a convoluted and complicated knot. Along with the nucleus were expelled multitudes of very minute corpuscles with active Brownian movements.

In a still further stage the nucleus had become irregularly branched, and at the same time somewhat thicker and of a softer consistence; and finally, it had become broken up into spherical fragments, each with an included corpuscle resembling a true cell nucleus in which the place of a nucleolus was taken by a cluster of minute granules.

In this case the original nucleus of the Vorticellidan had thus become broken up into bodies identical with the so-called eggs of Balbiani, but this was unaccompanied by any conjugation or by the formation of anything which could be compared to spermatozoal filaments.

What I believe we may regard as now established in the phenomena of reproduction in the Infusoria is, that besides the ordinary reproduction by spontaneous fission of the entire body, the nucleus at certain periods, and after more or less change of form has occurred in the Infusorium body, becomes broken up into fragments, each including a corpuscle resembling a true cell nucleus; and that this takes place without necessarily requiring the influence of conjugation or the action of spermatozoa; that these fragments after their liberation from the body of the Infusorum become developed—still without the necessity of spermatic influence—directly or indirectly into the adult form.

Whether proper sexual elements ever take part in the life history of the Infusoria remains an open question.

Everts ‡ has given an account of observations which, with the view of testing the statements of Greeff, he made on *Vorticella nebulifera*. Greeff, as we have seen, followed Claparede and Lachmann in attributing to the Vorticellæ a true cœlenterate structure; and Everts, by his own investigations, has convinced himself of the untenableness of this view, and has been led to regard the Vorticellæ as strictly unicellular.

He recognises the distinction between the cortical layer (which forms not only the periphery of the body but the whole of the stalk on which this is supported), and the central mass in which the nutriment is deposited, collected into pellets and digested; but instead of regarding this central mass as chyme, he looks upon it as an integral constituent of the entire body, like the central portion of an Amœba. The nucleus is imbedded in the inner side of the cortical layer, which is itself differentiated into certain secondary layers. He describes the deeper part of the cortical layer as exhibiting a rotation of its granules independent of the rotation which occurs in the central parenchyma, and moving in a direction opposite to that of the latter. Everts's account of the structure of Vorticella is thus in accordance with the conception of it as a cell with a parietal nucleus; a cell, however, in which differentiation is carried very far without the essential character of a simple cell being thereby lost.

Everts regards the external wall as corresponding with the ectoderm, and the internal softer body-substance with the endoderm of higher animals. If by this the author meant to indicate a homological identity between the structures thus compared, it is plain that he would have taken an entirely mistaken view based on a misconception of the essential nature of an ectoderm and endoderm. These membranes are essentially multicellular, and are always results of the segmentation of the vitellus in a true ovum. They can therefore never be attributed to a unicellular animal, in which no true segmentation process ever takes place. In his rejoinder, however, to an elaborate criticism of his memoir by Greeff, he explains that he intended to compare the two layers of the Infusorium body analogically, not morphologically, with an ectoderm and endoderm.

The same author has further made some interesting observations on the development of Vorticella. He has noticed that reproduction is here ushered in by a longitudinal cleavage, in which after division of the nucleus the body of the Vorticella becomes cleft into two halves, still seated on the common stalk. Each of these develops near its posterior end a wreath of vibratile cilia, while the peristome and the cilia-disc over the mouth are entirely withdrawn, and then breaks loose from its stem and swims freely away. These free-swimming Vorticellæ now encyst themselves, the cilia disappear, and the contents of the encysted animal acquire a uniform clearness with the exception of the nucleus, which persists unchanged. In the next place the nucleus breaks up into eight or nine pieces, and then the wall of the cyst becomes ruptured and gives exit to these fragments, which now appear as spontaneously moving spherules. These increase in size, develop on one end a cilia wreath, within which a mouth makes its appearance, and the free-swimming nucleus-fragment becomes gradually changed into a form which entirely agrees with the *Trichodina grandinella* of Ehrenberg.

These Trichodinæ now multiply by fission, first developing a posterior wreath of cilia, and then dividing transversely between the anterior and posterior wreaths. After this each fixes itself by the end on which the mouth is situated; a short stem becomes here developed, and the cilia wreath gradually disappears. Then upon the free end the peristome and cilia disc make their appearance, and the growth of the stem completes the development.

Everts remarks that in this process we have an example of alternation of generations. There is one point, however, in which he has overlooked its essential difference from a true alternation of generations, namely, the absence of any intercalation of a proper sexual reproduction.

Ray Lankester * has subjected to spectrum analysis the blue colouring matter of *Stentor cæruleus*. This occurs in the form of minute granules in the cortical layer of the animal, and Lankester finds that it gives two strong absorption bands of remarkable intensity, considering the small quantity of the matter which can be submitted to examination. He cannot identify these bands with those of any other organic colouring matter, and to the peculiar pigment in which he finds them he gives the name of *stentorin*.

He has also examined the bright green colouring matter of *Stentor Mülleri*, and finds that instead of giving the stentorin absorption bands, it gives a single band like that of the chlorophylloid matter of *Hydra viridis* and of Spongilla.

Ray Lankester † has also described, under the name of *Torquatella typica*, a remarkable marine Infusorium, which, though quite destitute of true cilia, can scarcely be separated from the proper Ciliata. With the general structure of the ciliate Infusoria, the place of a peristomal cilia wreath is taken by a singular plicated membrane, which forms a wide, frill-like, very mobile appendage, surrounding the oral end of the animal, and projecting to a considerable distance beyond it. The author regards *Torquatella typica* as the type of a distinct section of the Ciliata to which he gives the name of *Calycata*.

Of all the authors who since Von Siebold have applied themselves

* Quart. Journ. Mic. Sci., 1873.

† Ibid. 1874.

to the investigation of the Infusoria, Haeckel must be mentioned as the one who has brought the greatest amount of evidence to bear on the question of their unicellularity. In a very elaborate paper which has quite recently appeared,* and which is remarkable for the clearness and logical acuteness with which the whole subject is treated, Prof. Haeckel, resting mainly on the observations of others, and partly also on his own, argues in favour of the unicellularity of the Infusoria from the evidence afforded both by the phenomena of their development and by the structure of the mature organism. He confines himself chiefly to the Ciliata—which, indeed, he regards as the only true Infusoria—while he considers the unicellularity of the Flagellata as too obvious to require an elaborate defence. The value of this paper will be obvious from the analysis of it which I now propose to give.

In stating the argument derived from development, Haeckel does not accept as established the alleged sexual reproduction of the Infusoria, and he believes it safest to regard as non-sexual "spores" the bodies (*Keimkugeln*) which result from the breaking up of the nucleus, and which Balbiani regarded as eggs.

These bodies consist of a little mass of protoplasm usually destitute of membrane, and including a nucleus within which one or more refringent granules admitting of comparison with a true nucleolus may sometimes be witnessed—characters which are all those of a simple genuine cell. From this spore the embryo is developed by direct growth and differentiation of parts; but however great may be the differentiation, there is never anything like the formation of a tissue.

The development of the Infusoria is thus entirely in favour of the unicellular theory. This theory, however, is just as strongly supported by the study of their mature condition; and here Haeckel gives an admirable exposition of the structure of the true or Ciliate Infusoria.

The parts which are common to all Ciliata and which first differentiate themselves in the ontogenesis or development of the spore, are the cortical layer, the medullary parenchyma, and the nucleus, which is situated on the boundary between the two. The differentiation of the protoplasm of the naked spore into a clearer and firmer cortical substance, and a more turbid, granular, and softer medullary substance, corresponds entirely with what we see in the parenchyma cells of higher animals. These two products of differentiation are designated by Haeckel "exoplasm" and "endoplasm."

The exoplasm is originally a perfectly homogeneous and structureless, colourless hyaline layer distinguishable from the turbid granular soft protoplasm of the internal body mass, by containing in its composition less water, by absence of included granules, and by its high independent contractility. All the mobile appendages of the body, the cilia, bristles, spines, hairs, hooks, &c., are nothing but structureless extensions of this exoplasm and participate in its contractility. In this respect they entirely correspond to the cilia and flagellæ of the cells which form the ciliated epithelium of multicellular animals.

In many Ciliata we find this cortical layer or exoplasm itself subsequently differentiated into distinct strata. In the most highly differentiated Ciliata four layers may be distinguished as the result of this secondary differentiation of the exoplasm. These are: (1) the cuticle layer, (2) the cilia layer, (3) the myophan layer, (4) the trichocyst layer.

The *cuticle* is nothing but a lifeless exudation from the surface. In the majority of Ciliata there is no true cuticle, and in those which possess it, it presents itself under various forms, as seen in the thin, chitine-like, hyaline homogeneous pellicle of Paramæcum and Trichodina, the outer elastic layer of the stem of the Vorticellinæ, the protective sheath of Vaginicola, the chitin-like cases of the Tintinnodeæ and Codonellidæ, the beautiful lattice-like siliceous shells of the Dictyocystidæ, and many other shells, cases, and shield-like protections.†

The *cilia layer* occurs in all Ciliata; it lies immediately beneath the cuticle where this is present, and the whole of the cilia and other mobile appendages are its immediate extensions. These must therefore perforate the cuticle or its modifications when such protective coverings exist.

The *myophan layer* is identical with that which most authors describe as a true muscular layer. It has been demonstrated in most of the Ciliata. It appears as a system of regular parallel fine striæ in the walls of the body, and in the Vorticellidæ occupies also the axis of the stem, where it forms the characteristic "stem-muscle" of these animals. There can be no doubt that these striæ represent contractile fibrils, which, by their contraction, effect the various form changes of the animal. They are thus *physiologically* analogous to muscles. From a *morphological* point of view, however, we must regard them as only differentiated protoplasm filaments. In the morphological conception of true muscle, its cell nature is absolutely indispensable. The so-called muscle-fibrils of the Infusoria never show a trace of nucleus. They can be viewed only as *parts* of a cell due to the differentiation of the sarcode molecules of its protoplasm; and as they are thus only sarcode filaments, Haeckel designates them by the term "myophan," as indicating a distinction from proper muscle.

The *trichocyst layer* occurs also in many Infusoria, but not in all. It is a thin stratum of the exoplasm lying immediately on the endoplasm, and including in certain species the trichocysts. The presence of these bodies, which possess a striking resemblance to the thread-cells of the Cœlenterata, has, as we have already seen, been urged as an argument in favour of the multicellularity of the Infusoria. But, as Haeckel argues, no evidence of multicellularity can be derived from this fact. The thread-cells of the Cœlenterata are themselves the products of a cell, and we often find many of them originating in a single formative cell quite independently of the nucleus; the formative cell may in this respect be compared with the entire body of the Infusorium.

It is the endoplasm, or internal parenchyma of the Infusoria that has given rise to the most important differences of opinion, and in his account of this part of the Infusorium-organism Haeckel chiefly directs his criticism against the views advocated by Claparede and Lachmann, and by Greeff.

These authors, as we have already seen, compare the Infusoria with the Cœlenterata, and regard the endoplasm not as a real part of the body, but merely as the contents of the alimentary canal—as a sort of food mash or chyme contained in a spacious digestive cavity whose walls are at the same time stomach wall and body wall, and into which the mouth leads by a short gullet. As Haeckel urges, however, it needs only a correct conception of the intestinal cavity throughout the animal kingdom and of its distinction from the body cavity, in order to show the untenableness of this position. The main point of such a conception lies in the fact that the intestinal cavity and all extensions of it (gastro-vascular canals, &c.) are always originally clothed by the endoderm or inner leaflet of the blastoderm, while the body cavity is always formed on the external side of the endoderm, and between this and the ectoderm or outer leaflet of the blastoderm. The body cavity and intestinal cavity of animals are thus essentially different; they never communicate with one another, and always arise in quite different ways.

Again, the contents of a true intestinal cavity consist only of nutritious matter and water, in other words, of chyme; while the fluid which fills the body cavity is never chyme, but is always a liquid which has transuded through the intestinal wall, and which may be called chyle, or blood in the wider sense of the word.

Haeckel has thus taken, I believe, the true view of the intestinal and body cavities of animals. He had already advocated it in his work on the Calcareous Sponges. It necessarily in-

* Haeckel, "Zur Morphologie der Infusorien." Jenaische Zeitschr., Band vii. heft 4, 1873.

† In the same number of the *Zeitschrift*, Haeckel ("Ueber einige neue pelagische Infusorien") describes some highly interesting Infusoria which spend their lives in the open sea and are distinguished by the possession of variously formed shells. His attention was first directed to them by finding their elegant empty shells in the extra-capsular sarcode of Radiolariæ. These pelagic Infusoria appear to belong to two different groups, which stand nearest to the Tintinnodeæ of Claparede and Lachmann. He designates them as *Dictyocystidæ* and *Codonellidæ*.

The family of the Dictyocystidæ is based on Ehrenberg's *Dictyocysta*, and is characterised by the possession of a siliceous perforated lattice-like shell so closely resembling that of many Radiolariæ, that Haeckel at first mistook it for the shell of one of these. The shell is in all the species bell-shaped or helmet-shaped, and the body of the animal, which is fixed to the fundus of the bell, and can be projected far beyond its margin, has a wide funnel-shaped peristome on whose edge are two concentric wreaths of strong cilia. He describes four species, distinguishing them by characters derived from their siliceous latticed shell.

The family of the Codonellidæ, based on the genus *Codonella*, Haeckel, is also provided with a bell-shaped case, but this, instead of being formed of a siliceous lattice work, consists of a chitine-like organic membrane, through which siliceous particles are scattered. The family is, however, chiefly characterised by the peculiar form of its peristome. This is funnel-shaped and provided on its margin with a thin collar-like expansion. The free edge of this collar is serrated, and each tooth carries a stalked lobe of a piriform shape, regarded by Haeckel as probably an organ of touch. At some distance behind the circle of piriform lobes is situated a ring of long, strong, whip-like cilia, which form powerful swimming organs. The three species described are distinguished by the form of their chitinous cases.

volves a belief in the homological identity of organisation between very distant groups of the animal kingdom, a belief which all recent embryological research has only tended to confirm.

(*To be continued.*)

SCIENTIFIC SERIALS

American Journal of Science and Arts, June.—The original articles in this number are :—Results of dredging expeditions of the New England Coast in 1874, by A. E. Verrill. More than 100 species new to the fauna of southern New England were secured. Most of these are northern species, but many are undescribed. A table giving nature of bottom and temperature at the surface and bottom of the sea is given.—Mr. Fontaine's paper on the Primordial Strata of Virginia is continued and concluded. At the end is given a comparison with the metamorphic crystalline rocks of the Blue Ridge.—On the occurrence of the Brown Hematite deposits of the Great Valley, by Frederick Prime, jun.—Note on some new points in the elementary stratification of the Primordial and Canadian rock of south central Wisconsin, by Roland Irving. The order for the Lower Silurian strata of Wisconsin has been generally accepted as (beginning from below) 1. Potsdam sandstone ; 2. Lower magnesian limestone ; 3. The St. Peter's sandstone ; 4. The blue and buff limestones ; 5. The Galena limestone ; 6. The Cincinnati group. The succession as now made out is (beginning from below) 1. The Lower or Potsdam sandstone ; 2. The Mendota limestone ; 3. The Madison sandstone ; 4. The main body of limestone ; 5. The St. Peter's sandstone. A table of correlation is given with the Mississippi Bluffs and the Minnesota River.—On the application of the horizontal pendulum to the measurement of minute changes in the dimensions of solid bodies, by Prof. O. N. Rood.—On diabantite (a chlorite), by G. W. Hawes.—Re-discovery of double star H.I. 41, by S. W. Burnham. It is about 46′ north of the well-known double star ψ' Draconis, and is easily found without an equatorial mounting.—On the distribution of electrical discharges from circular discs, by C. J. Bell.—Examination of gases from the meteorite of Feb. 12, 1875, by A. W. Wright.—On limonite with the colour and transparency of göthite, by Prof. Mallet.—Under the head "Scientific Intelligence," the original notes are :—On the surface geology of Ohio ; On the Prototaxites of Dawson ; On the Crustaceans of the caves of Kentucky and Indiana, together with several reviews.

Fourth and Fifth Annual Reports of the Wellington College Natural History Society, Dec. 1872 to Dec. 1874.—We are gratified to see that this Society is in a much more hopeful condition than it was when we noticed its last Report, the tone of which was almost despairing. The attendance has been very much better, and the interest taken in the Society by the boys is evidently increasing. Judging from the lists a fair amount of field-work in natural history has been done, and the Society is gradually forming good collections. But, as the preface to one of the Reports hints, there is still much room for improvement in the subjects and character of the papers read at the meetings. Except in the case of lectures by outsiders, the majority of the papers are the result of reading and not of observation or experiment, and not many of them can strictly be called scientific. Now, however useful such exercises as these may be to the boys, this is scarcely the sort of work one looks for from members of a Natural History Society. We think this Society might well take a leaf out of the Rugby Society's Report, and go in much more extensively for organised field-work, encouraging the boys to use their eyes and their hands on nature as well as on books, and to bring forward papers embodying the results of their observations, papers of a character similar to the interesting one of the president, the Rev. C. W. Penny, on "Natural History in the Christmas Holidays." Not only would the members thus reap much benefit, both in the way of discipline and instruction, but we are sure a greater interest in the Society would be created in the School. The Society has evidently got a good second start, and we trust that the next Report will show as great an advance on the two under notice as these do on the previous one.

Riga Society of Naturalists.—Nos. 8 and 9 of this Society's publications contain three papers of importance, besides meteorological reports and notes of smaller interest. The more important papers are : On some theories of earthquakes, by Prof. Schweder.—On the changes in the Düna estuary, by M. Gottfried.—On the fauna of Spitzbergen, by Prof. Nordenskjöld, showing that this fauna consists of 15 species of quadrupeds, 23 of birds, 23 of fishes, 64 of insects, 100 of Crustaceæ, and 130 of sea molluscs.—There is also an obituary notice of the late Dr. Ernst Nauck, who died at Riga on Jan. 26 last.

SOCIETIES AND ACADEMIES

London

Royal Society, June 10.—"Experiments on Stratification in Electrical Discharges through Rarefied Gases," by William Spottiswoode, M.A., Treas. R.S.

In the stratified discharges through rarefied gases produced by an induction-coil working with an ordinary contact-breaker, the striæ are often unsteady in position, and apparently irregular in their distribution. Observations made with a revolving mirror, which the author hopes to describe on another occasion, have led him to conclude that an irregular distribution of striæ does not properly appertain to stratification, but that its appearance is due to certain peculiarities in the current, largely dependent upon instrumental causes.

The beautiful and steady effects obtained by Mr. Gassiot with his Leclanché battery, and also more recently by Mr. De la Rue with his chloride-of-silver battery, have abundantly shown the possibility of stratification free from the defects above mentioned ; but it must be admitted that the means employed by those gentlemen are almost gigantic. The present experiments were undertaken by the author with the view of ascertaining, first, how far it was possible to approach towards similar results with instruments already at his command ; and secondly, whether these would afford other modes of attack, beside the battery, on the great problem of stratified discharges.

The induction-coil used was an "18-inch" by Apps, worked occasionally by six large chloride-of-silver cells, kindly lent the the author by Mr. De la Rue, but more usually by ten or by twenty Leclanché cells of the smallest size ordinarily made by the Silvertown Company. He has also, in connection with the same coil, 120 of the latter cells, connected in twenties for quantity, and forming six cells of twenty times the surface of the former. These work the coil with the ordinary contact-breaker very well, giving 11-inch sparks whenever required. A "switch" affords the means of throwing any of the three batteries in circuit at pleasure.

Having reason to think that the defects in question were mainly due to irregularity in the ordinary contact-breaker, he constructed one with a steel rod as vibrator, having a small independent electromagnet for maintaining its action. The details of construction of this contact-breaker are described.

With a contact-breaker of this kind in good action, several phenomena were noticeable ; but first and foremost was the fact that in a large number of tubes (especially hydrocarbons), the striæ, instead of being sharp and flaky in form, irregular in distribution and fluttering position, were soft and rounded in outline, equidistant in their intervals, steady in proportion to the regularity of the contact-breaker. These results are, the author thinks, attributable more to the regularity than to the rapidity of the vibrations. And this view is supported by the fact that, although the contact-breaker may change its note (as occasionally happens), and in so doing may cause a temporary disturbance in the stratification, yet the new note may produce as steady a set of striæ as the first. And not only so, but frequently there is heard, simultaneously with a pure note from the vibrator, a strident sound, indicating that contacts of two separate periods are being made, and yet, when the strident sound is regular, the striæ are steady. On the other hand, to any sudden alteration in the action of the break (generally implied by an alteration in the sound) there always corresponds an alteration in the striæ.

The author then attempts to show the extreme delicacy in action of this kind of contact-breaker, or "high break," as it may be called.

The discharges described above are usually (although not always) those produced by breaking contact ; but it often happens, and that most frequently when the strident noise is heard, that the current produced by making contact is strong enough to cause a visible discharge. This happens with the ordinary as with the high break ; but in the latter case the double current presents the very remarkable peculiarity, that the striæ of one current are so arranged as to fit exactly into the intervals of

the other. And further, that any disturbance affecting the column of striæ due to one current affects similarly, with reference to absolute space, that due to the other, so that the double column moves, if at all, as a solid or elastic mass. And this fact is the more remarkable if we consider, as is easily observed in a revolving mirror, that these currents are alternate, not only in direction, but also in time, and that no one of them is produced until after the complete extinction of its predecessor. And it is also worthy of note that this association of striæ is not destroyed, even when the two currents are separated more or less towards opposite sides of the tube by the presence of a magnetic pole. There seems, however, to be a tendency in that case for the striæ of one current to advance upon the positions occupied by those of the reverse current, giving the whole column a twisted appearance. But as there is no trace, so far as the author's observations go, of this association of alternate discharges when produced by the ordinary break, we seem led to the conclusion that a stratified discharge, on ceasing, leaves the gas so distributed as to favour, during a very short interval of time, a similar stratification on the occurrence of another discharge, whether in the same or in the opposite direction. An explanation of the fact that the striæ of alternate discharges occupy alternate and not similar positions is not obvious, and probably demands a better knowledge of the nature of the striæ than we possess at present.

The column of striæ, which usually occupy a large part of the tube from the positive towards the negative terminal, have hitherto been described as stationary, except as disturbed by irregularities of the break. The column is, however, frequently susceptible of a general motion, or "flow," either from or towards the positive pole, say a forward or backward flow. A similar phenomenon was observed by Mr. Gassiot in some tubes with his large battery, but the author is not acquainted with the exact circumstances under which it was produced. This flow may be controlled, both in velocity and in direction, by resistance introduced into the circuit, or by placing the tube in a magnetic field. The resistance may be introduced in either the primary or the secondary circuit. For the former arrangement the author successfully employed a set of resistance-coils, supplemented by a rheostat. For the secondary current, as well as for the Holtz machine, he has used an instrument devised and constructed by his assistant, Mr. P. Ward, to whose intelligence and skill he is much indebted throughout this investigation, intended for fine adjustment. Wherever the resistance be introduced the following law appears to be established by a great number and variety of experiments, viz., that, the striæ being previously stationary, an increase of resistance produces a forward flow, a decrease of resistance a backward flow. The author has generally found that a variation of 3 or 4 ohms, or, under favourable conditions, of 1 or 2 ohms, is sufficient to produce this effect. But as an alteration in the current not only affects the discharge directly, but also reacts upon the break, the effect is liable to be masked by these indirect causes. The latter, so far as they are dependent upon a sudden alteration of the resistance, may be diminished by the use of the rheostat; but when the striæ are sufficiently sensitive to admit the use of this delicate adjustment, some precautions are necessary to ensure perfect uniformity of current, so as to avoid disturbances due to uneven contact in the rheostat itself.

When the striæ are flowing they preserve their mutual distances, and do not undergo increase or decrease in their numbers. Usually one or two remain permanently attached to the positive electrode; and as the moving column advances or recedes, the foremost stria diminishes in brilliancy until, after travelling over a distance less than the intervals between the two striæ, it is lost in darkness. The reverse takes place at the rear of the column. As the last stria leaves its position, a new one, at first faint and shadowy, makes its appearance behind, at a distance equal to the common interval of all the others. This new one increases in brilliancy until, when it has reached the position originally occupied by the last stria, when the column was at rest, it becomes as bright as the others. The flow may vary very much in velocity; it may be so slow that the appearances and disappearances of the terminal striæ may be watched in all their phases, or it may be so rapid that the separate striæ are no longer distinguishable, and the tube appears as if illuminated with a continuous discharge. In most cases the true character of the discharge, and the direction of the flow, may be readily distinguished by the aid of a revolving mirror. In some tubes, especially in those whose length is great compared with their diameter, the whole column does not present the same phase of flow; one portion may be at rest while another is flowing, or even two conterminous portions may flow in opposite directions. This is seen also in very wide tubes, in which the striæ appear generally more mobile than in narrow ones. But in all cases these nodes or junction-points of the flow retain their positions under similar conditions of pressure and current; and it therefore seems that, under similar conditions, the column in a given tube always breaks up into similar flow-segments.

These nodes will often disappear under the action of a magnetic pole. Thus, if the first segment, measured from the positive terminal, be stationary and the second be flowing backwards (*i.e.* from − to +), a magnetic pole of suitable strength, placed at the distant end of the latter, will stop its flow, and the whole column will become stationary throughout. An increase in the strength of the magnet, or a nearer approach of it to the tube, will produce a general forward flow of the column.

The phenomena of the flow, as well as others of not less interest, are capable of being produced with the Holtz machine. It is well known that stratified discharges, similar to those produced by an induction-coil working with an ordinary break, may be produced by such a machine, provided that it be furnished with the usual Leyden jars, and a high resistance (usually a piece o. wetted string) be interposed in the circuit. The absence of either of these conditions was supposed to destroy the striæ and to render the discharge continuous. Experiments which the author has recently made, but do not describe on the present occasion, tend in part, but only in part, to confirm this view. They show that for the production of striæ both quantity and resistance are necessary, that the discharge must occupy a certain short, perhaps, but finite time, or, as it may also be expressed, that a continuous current is an essential element.

Now, seeing that every tube must offer some resistance, and also that by adjusting the height of the vertical condensors of the machine (or length of air-spark interposed in the circuit) we had the means of altering the quantity in the discharge, it seemed worth while to try whether, by a suitable adjustment of the parts, phenomena similar to those brought out by the coil and high break might not be produced by the machine. And this proved to be very easy of attainment in tubes which had been successfully used by the coil; and not only so, but the character of the flow therein shown confirmed in a very striking and simple manner the effects of resistance described above.

The connections being made in the usual way, and no air-spark being admited into the circuit, a vacuum-tube of carbonic oxide, about 60 centims. in length and 4·5 centims. in outside diameter, gave, when the plates of the machine revolved at about six times per second, a rather confused discharge. As the speed was increased a rapid forward flow of the striæ was readily discerned; and on a still further increase to about ten revolutions per second, the flow, first in one part and then throughout nearly the whole length of the tube, slackened its pace and stopped, and ultimately reversed its motion. An increase of speed is equivalent to an overcoming or a diminution of resistance in the circuit, a diminution of speed to an augmentation of resistance. Hence the phenomena of flow produced by the machine agree with those produced by the coil.

The author concludes by referring to the effects obtained with sulphurous acid and other tubes, and by describing the resistance-coil used for the secondary current.

Chemical Society, June 17.—Prof. Abel, F.R.S., in the chair.—Notes on the chemistry of tartaric and citric acid, by Mr. R. Warrington, gives many important particulars connected with the manufacture of these acids: and also detailed accounts of the methods of analysis—many of them novel—of the various raw materials from which they are made.—After this the Secretary read a communication on the action of nitric acid on copper, mercury, &c., especially in the presence of metallic nitrates, by Mr. J. J. Ackworth.—Dr. Gladstone then gave a short account of the decomposition of water by the joint action of aluminium and aluminium iodide, bromide, and chloride, including instances of reverse action, by himself and Mr. Tribe.—The other papers were on nitrosyl-bromide and on sulphuro-bromide, by Mr. M. M. P. Muir.—On achrematite, a new molybdo-arseniate of lead from Mexico; and on certain new reactions of tungsten, both by Prof. J. W. Mallet; and on the action of chlorine on acetamide, by Dr. Prévost.

Geological Society, June 9.—John Evans, V.P.R.S., president, in the chair.—The following communications were read:

—On *Prorastomus sirenoïdes*, Owen. (Part II.), by Prof. Owen, F.R.S. The author has submitted the skull of a Sirenian from Jamaica, described by him in 1855 under the name of *Prorastomus sirenoïdes*, to a careful re-examination; and in this paper notices the characters revealed by further removal of the matrix, and discusses the bearings of the facts thus ascertained upon the relations of the animal and of the Sirenia generally. The parts which have been brought to light are the base and roof of the cranium, the zygomatic arches, the hind half of the mandible, with the articular part of the condyle, and the greater part of the atlas. The characters presented by these parts are described in detail, and the characters of the genus are compared with those presented by other genera of Sirenians, both living and fossil, especially *Manatus* and *Felsinotherium*. The dental formula of *Prorastomus* is given as—

$$i.\ \frac{3-3}{3-3}?,\ d.\ \text{or}\ c.\ \frac{1-1}{1-1},\ p.\ \frac{5-5}{5-5},\ m.\ \frac{3-3}{3-3} = 48:$$

thus, as in *Manatus*, showing an excess in the molar series over the type of the terrestrial herbivorous mammalia, whilst the incisors and canines retain the common type as to number and kind, and have not been subjected to so great a degree of suppression or of individual excess of development as in existing Sirenians. The presence of these small subequal incisorsin both jaws of *Prorastomus* is the most marked feature in which *Prorastomus* adheres to the normal mammalian type, while showing the essential characters of the marine Herbivores; but a similar tendency is shown in other parts of the skull. The author regards the Sirenia as essentially monophyodont. *Halicore* and *Felsinotherium* depart further from the type than *Halitherium* and *Manatus*, and these than *Prorastomus*. *Rhytina*, with a better developed brain and with the jaws edentulous when adult, is an extreme modification of the Sirenian type. The rudimentary femur in *Halitherium* is to be regarded as the result of degeneration through lack of use, from better-limbed prototypal mammals. With respect to the genealogy of the Sirenia, the author remarks that Häckel derives the Sirenia, Zeuglodontes, and Cetacea, together with the Artiodactyla, from the branch Ungulata, and the Perissodactyla from the branch Pycnoderma of the Mammalian trunk; but that while *Halitherium* and *Felsinotherium* show the molar pattern of *Hippopotamus*, *Prorastomus* exhibits that of *Lophiodon* and *Tapirus*, to which *Manatus* also adheres rather than to any Artiodactyle type. The author suggests that both Ungulates and Sirenians diverged at some remote period from a more generalised (cretaceous?) mammalian gyrencephalous type? and that the marine Herbivora in the course of long Eocene and Miocene eons were subjected to conditions producing modifications of their molars, leading on one side to an Artiodactyle and on the other to a Perissodactyle character. As *Prorastomus* by its more generalised dentition and shape of brain represents a step nearer the speculative starting-point than any other Sirenian, it acquires a great interest, and the determination of the precise age of the (supposed Eocene) bed from which its remains were derived is very much to be desired.—On the structure of the skull of *Rhizodus*, by L. C. Miall, F.G.S. In this paper the author described a large skull of *Rhizodus* from the coal-shale of Gilmerton, near Edinburgh. The characters described show that *Rhizodus* is a Ganoid fish, and that its position in the order is not far from *Holoptychius* and *Megalichthys*. The author referred it to the cycloidal division of the family Glyptodipterini.—Appendix to a note on a modified form of Dinosaurian Ilium, hitherto reputed Scapula, by Mr. J. W. Hulke, F.R.S.—This paper contained a notice of the pubis of *Iguanodon*, which proves to be identical with the smaller of the two specimens figured by the author in a former paper (Quart. Journ. Geol. Soc. xxx. pl. xxxii. Fig. 1). When inverted, its long slender process is easily identified with that of the pubis of the nearly allied *Hypsilophodon*, and this slanted downwards and backwards parallel to the ischium, the little process of its posterior surface, meeting a corresponding process of the ischium, and converting the upper end of a long narrow obturator space into a foramen. The pubis of *Iguanodon* contributed largely to the formation of the acetabulum, thus resembling that of existing Lacertilia, as also in its possession of a broad ventral extension, probably united with that of the opposite side by a median symphysis. The specimens described in this paper were collected in the Isle of Wight by the Rev. W. Fox.—Notes on the Palæozoic Echini, by Mr. Walter Keeping, of the Woodwardian Museum, Cambridge; communicated by Prof. T. M'Kenny Hughes, F.G.S. The author alluded to the interest excited by the discovery of Echinoderms with flexible tests; and having pointed out the difference between the more modern and the Palæozoic forms (their plates imbricating in opposite directions), gave a description of the following forms:—(1) *Perischodomus*; (2) *Ræchinus*, g.n., sp. *R. irregularis* (Keeping); (3) *Palæchinus* (?) *intermedius* (Keeping); (4) *Palæchinus gigas* (McCoy); (5) *Palæchinus sphæricus* (McCoy); (6) *Archæocidaris Urii* (Fleming). In conclusion, the author proposed a new method of classification for the *Echinoidea*. He also noticed the existence in the Museum of the Royal School of Mines of a British fossil which appears to belong to the group of Echinoidea with numerous ranges of ambulacral plates, represented in America by the genera *Melonites*, *Oligoporus*, and *Lepidesthes*.—On some fossil Alcyonaria from the Australian Tertiary deposits, by Prof. P. Martin Duncan, F.R.S. In a former communication in 1870 the author described some fossil corals from the Tertiary strata near Cape Otway, in the province of Victoria. In one, which he called the "Upper Coralline bed," the equivalent of the Polyzoan limestone of Woods, he found specimens which he did not then describe, as they were not true corals. Belonging to the Isidinæ, and not being of great interest, he retained them until the receipt of some similar specimens from New Zealand, described in the following paper. The Australian forms described by the author were shown to be nearly allied to the recent *Isis hippuris* and the fossil *I. corallina*.—On some fossil Alcyonaria from the Tertiary deposits of New Zealand, by Prof. P. Martin Duncan, F.R.S. The New Zealand fossils referred to in the preceding paper were sent to the author by Capt. F. W. Hutton, F.G.S.; they were derived from the Awawoa Railway cutting, and were from the upper part of the Oawaru formation. They consisted of fragments of species of the genus *Isis* and of *Corallium*. These were compared with those from the Australian Tertiaries, and the author inferred that both deposits were formed under similar conditions, and that they were at least homotaxial, whatever their precise geological age might be.—On some fossil corals from the Tasmanian Tertiary deposits, by Prof. P. Martin Duncan, F.R.S. The author described a new species of *Dendrophyllia* possessing very unusual characters, the epitheca replacing the true wall, and giving the specimen a marked Palæozoic appearance. The fossil was obtained from a Tertiary deposit, and was associated with *Placotrochus deltoideus*, a well-marked coral, characteristic of a definite geological horizon in Victoria, namely, the lower beds of the Cape Otway section, belonging to the Lower Cainozoic period. For this coral he proposed the name of *Dendrophyllia epithecata*. A much worn reef-coral was found associated with the above.

Meteorological Society, June 16.—Dr. R. J. Mann, president, in the chair.—The following papers were read:—On a white rain or fog bow, by Mr. G. J. Symons.—On a proposed form of thermograph, by Mr. Wildman Whitehouse, F.R.A.S.—On the rainfall at Athens, by Prof. V. Raulin (translated by Mr. R. Strachan). These observations were made by M. Julius Schmidt, director of the Greek Observatory, and embrace a period of twelve years and a half, viz., from August 1859 to December 1871. The average yearly fall is 15·83 inches, and the average number of wet days ninety-three. The wettest year was 1864, when 28·30 inches fell, and the driest 1862, with 9·63 inches.—On the barometric fluctuations in squalls and thunderstorms, by the Hon. Ralph Abercromby. There are two classes of storms in this country: in one the barometer rises, in the other it falls. The author in the present paper only refers to the former. After mentioning some of the phenomena which accompany storms of this class, he proceeds to give two instances as typical of their general character. In conclusion he makes the following remarks on their origin:—Though in this country squall-storms are almost always associated with primary or secondary cyclones, those in India and Africa are not connected with cyclones, and hence the source of the barometric rise cannot be due to any special phenomenon of cyclone motion. Since the rise is always under the visible storm, it is propagated at the same rate and in the same manner as thunderstorms. Enough is known of the course of the latter to be certain that they are not propagated like waves or ripples, and hence these small barometric rises are not due to aërial waves, as has sometimes been suggested. Since the general character of the rise is the same whether there is thunder or not, it is evident that electricity, even of that intensity which is discharged disruptively, is not the cause of the rise. If we look at a squall from a distance, we always see above it cumulus, which is harder and more intense in the front than in the rear of the squall. Since cumulus is the condensed summit of an ascensional column of

air, it is evident that the barometric rise takes place under an uptake of air. If we consider further that a light ascensional current would give rise simply to an overcast sky, a stronger one to rain, while a still more violent one would project the air suddenly into a region so cold and dry that the resulting electricity would be discharged disruptively as lightning, the foregoing observations show that the greatest rise is under the greatest uptake. Some meteorologists attribute the low pressure at the equator to the ascending current formed at the junction of the trades; while others attribute the 10 A.M. maximum of the diurnal range of the barometer to the reaction of an ascending column of air due to the increasing heat of the day. The above observations tend to strengthen the view that an ascending column of air gives rise to a reactionary pressure downwards, and more generally to the idea that though the total pressure shown by the barometer is principally statical, or due to the weight of a definite column of air, a small portion is dynamical, or due to the reaction of air motion in that column. —Notes on solar radiation in its relation to cloud and vapour, by Mr. J. Park Harrison.—Mr. Scott also exhibited and described Lowe's graphic hygrometer.

Zoological Society, June 15.—Prof. Newton, F.R.S., V.P., in the chair.—A letter was read from Dr. A. B. Meyer, of Dresden, stating that having inquired into the statement made by Mr. Bruyn (P.Z.S., 1875, p. 30), that he had specimens of four species of Birds of Paradise alive in his possession at Ternate, he had ascertained that the foundation for this statement was that Mr. Bruyn expected to receive specimens of other species, but had only actually obtained examples of one of them (*Paradisea papuana*).—Mr. George Dawson Rowley exhibited and made remarks on some specimens of two diminutive Parrots from New Guinea (*Nasiterna geelvinkiana* and *N. pygmæa*).—Sir Victor Brooke exhibited and made remarks on two original drawings by Mr. Wolf of the two species of Koodoo, *Tragelaphus strepsiceros* and *T. imberbis*. The latter was taken from a specimen received direct from the Juba River, Somali. The exact habitat of this species had not before been determined.—Prof. Owen, C.B., read a paper in which he gave the description of some bones of *Harpagornis moorei*, sent to him by Dr. Haast, which had been found in the turbary deposits of Glenmark, a locality about forty miles from Christchurch, New Zealand. This paper formed the twenty-first part of Prof. Owen's series of memoirs on the extinct birds of the genus *Dinornis* and its allies. —Mr. G. E. Dobson communicated the descriptions of some new species of bats of the genus *Vesperugo*.—A communication was read from Mr. George Gulliver, F.R.S., containing observations on the sizes and shapes of the red corpuscles of the blood of Vertebrates. These observations were accompanied by a series of drawings of these objects, and by extended and revised tables of measurements.—A communication was read from the Rev. S. J. Whitmee, of Samoa, respecting the changes he had observed in the habits of feeding, roosting, and building of the *Didunculus strigirostris*.—A second paper by Mr. Whitmee gave an account of the times of appearance of the Edible Marine worm (*Palola viridis*) in the islands of the Samoan group, together with observations on its habits.—A communication was read from Dr. J. S. Bowerbank, containing the fourth of a series of memoirs on the Siliceo-fibrous sponges.—Sir Victor Brooke, Bart., and Mr. A. Basil Brooke read a joint paper on the large Asiatic Wild Sheep or Argalis. Of these animals they recognised eight species, viz.: *Ovis ammon*, from the Altai between the Sea of Baikal and Thian Shan; *O. karelini*, from the Thian Shan; *O. poli*, from the Pamir; *O. hemsii*, from the Alexandrian Mountains; *O. nigrimontana*, from the Karatau; *O. hodgsoni*, from Little Thibet; *Ovis nivicola*, from the Stanovoi Mountains and Kamschatka; and *Ovis brookei*, of which the habitat was unknown.—Mr. Sclater read a paper on the Rhinoceroses now or lately living in the Society's Menagerie.

Victoria (Philosophical) Institute, June 21.—The Rev. Isaac Taylor, M.A., read a paper on the Etruscan language. After stating the causes which had made this language so long a mystery, the lecturer gave an account of the origin of the Etruscan alphabet, and of the information as to the nature of the language which is supplied by the bilingual inscriptions. He then gave an account of the inscribed dice, which he held to be the key to the Etruscan secret. He fully explained the Etruscan system of numeration, and showed that the numerals, the vocabulary, the grammar, and the mythology of this people all pointed to a Turanian origin.

PARIS

Academy of Sciences, June 14.—M. Frémy in the chair.—The following papers were read:—On the discovery of the two minor planets (144) and (145) by Director Peters, and (146) by M. Borrelly.—A note by M. Chevreul, on the explanation of numerous phenomena which appear as a consequence of old age.—Researches on solar radiation (continuation) by M. P. Desains.—On the synthesis of camphors by the oxidation of camphenes, by M. Berthelot.—On the water-spout which occurred near Caen in 1849, by M. Faye.—Some remarks, in complement to his note read before the Academy in May 1873 by M. Weddell, on the part played by the substratum in the distribution of Lichens inhabiting rocks.—A note by MM. E. Belgrand and G. Lemoine, on the probable decrease of flowing water in the basin of the Seine during the summer and autumn of 1875.—Report of the Commission which was appointed to examine a proposed new method in the construction of lightning conductors for powder magazines.—On the theory of revolution surfaces which, by way of deformation, can be superposed on one another, and each on itself in all its parts (second paper), by M. F. Reech.—A note by M. Sekowski, on a system of distribution in steam-engines.—On the synthesis of terpilene or carburetted camphene, by M. G. Bouchardat.—A note by M. Barthelemy, on a process to measure the co-efficient of the absolute dilatation of mercury.—A note by M. A. Rivière on the appearance of sedimentary formation in the granitic rocks now used for the pavements in the Paris streets.—A note by M. E. Jourdy on the shape of bays in the Algerian district.—A memoir by M. L. V. Turquan, on the integration of the equation with partial derivatives of the third order, and two independent variables.—A note by M. Lecoq de Boisbaudran, on the theory of dissolution and of crystallisation.—Report of the falling of two meteoric stones in the United States, by M. J. Lawrence Smith, of Louisville (Ky.). The author gives a minute description and an analysis of these two meteorites.—On the influence of forests upon the climate, and on the variation of temperature with the phases of vegetation, by M. L. Fautrat.

BOOKS AND PAMPHLETS RECEIVED

FOREIGN.—Annales del Museo Publico de Buenos Aires.—Annalen des Physikalischen Central Observatoriums for 1873: H. Wild (Russia).—Morphologisches Jahrbuch. Eine Zeitschrift für Anatomie und Entwickelungsgeschichte: C. Gegenbaur (Leipzig, W. Engelmann).—Die Neue Schöpfungsgeschichte: Arnold Dodel (Leipzig, F. N. Brockhaus).—Handbuch der Zoologie. 3 vols.: J. Victor Carus and C. E. A. Gerstaeker (Leipzig, W. Engelmann).—Boletin de la Academia Nacional de Ciencias Exactus existante en la Universidad de Cordoba, Buenos Aires.—Jahrbücher für Wissenschaftliche Botanik: Dr. N. Pringsheim (Leipzig, Wm. Engelmann).—Sie Alcundi Principj di Elettrostatica. Serie di Esperienze del Prof. G. Cantoni (Milan, F. Vallardi).—Salla Polarizzione dei Coibenti: Prof. G. CONTENTS

THURSDAY, JULY 1, 1875

SIR WILLIAM EDMOND LOGAN

By the death of this illustrious geologist and most genial man, science has been deprived of one of her bravest and best soldiers, while those who personally knew him have lost a true, warm-hearted friend.

One by one the magnates by whose toil geology rose during the first half of this century are taken from us. Link after link is broken in the chain of living men who have served to bind us personally with the birth and infancy of that science. Few were left to us, and of these few none more honoured and beloved than the veteran who has just been called away. Of Scottish parentage (his father having been a landed gentleman in Stirlingshire, who had emigrated to Canada), W. E. Logan was born at Montreal in the year 1798. He was sent home to the old country for his education, and studied, it is believed, both at the High School and the University of Edinburgh. Eventually, having developed an ardent love for geological pursuits, he settled in South Wales and began to study the structure of the great coal-field of that region. It was there that he fostered that habit of patient and exact observation, combined with quickness of eye in seizing the salient points in the geological structure of a region, which stood him in such good stead in later life. During a series of years he carefully followed the outcrops of the various coal-seams, tracing the positions of the numerous faults by which they are traversed, and putting all his data upon the one-inch sheet of the Ordnance Survey. These maps of the South Welsh coal-field were probably the first in this country, on so large a scale and of so extensive a district, where the details of geological structure were depicted with such minuteness. They were generously handed over to Sir Henry de la Beche when he began the Geological Survey in that region, and he found them so admirable that he adopted them for the Government Survey, on the early sheets of which the name of W. E. Logan is engraved in conjunction with those of De la Beche, Ramsay, Phillips, and Aveline. He worked on the staff of the Survey as an enthusiastic volunteer, lending invaluable assistance in the South Welsh region, and among other services introducing horizontal sections on a true scale of six inches to a mile, which served as models for the large sections of the Survey.

One of the most important observations made by Logan during this early part of his career was one relating to the origin of coal. He pointed out, what is now so universally recognised and yet does not seem ever to have struck anybody before, that each coal-seam rests upon an underclay or fireclay in which rootlets of *Stigmaria* branch freely in all directions. This association of coal and *Stigmaria*-clay he found to be so general that it could not be regarded as accidental. He suggested that the clay represented an ancient soil or mud in which the *Stigmaria* grew, and that the coal stood now in place of the matted vegetation which grew upon that soil. The value of this contribution to our knowledge of the history of coal and of the changes in physical geography to which the stratified rocks bear witness, can hardly be over-estimated.

In the summer of 1841 Mr. Logan went to America and spent the autumn of that year in explorations of the coal-fields there. He examined the Pennsylvanian region, which had been studied by Rogers, and afterwards went through the coal-districts of Nova Scotia, where he made some original observations. He spent the winter of 1841-1842 in Canada, devoting himself among other things to watching the behaviour of ice as a great geological agent on the rivers. In the spring of 1842 he took his place again at the Geological Society of London, and gave there some interesting details regarding what he had seen during his absence on the other side of the Atlantic.

About this time (1842) there arose in Canada a desire to know something more about the mineral resources of the colony, and the Legislature went so far as to vote a sum of 1,500*l.* for a geological survey. The Canadian authorities consulted the Home Government as to a suitable person to take charge of the undertaking, mentioning at the same time Mr. Logan's name, and requesting information as to the estimation in which his scientific qualifications were held in this country. Murchison happened at the time to be President of the Geological Society. The official request being forwarded to him, he recommended the proposed appointment in the warmest terms, as one that would "render essential service to Canada, and materially favour the advancement of geological inquiry." This testimony and doubtless the warm support of his old friend, De la Beche, led to Mr. Logan's appointment as organiser and director of the survey of the rocks and minerals of his native country.

From the commencement of this work in 1843 Mr. Logan's whole energies were given to the task which had been assigned to him, and never did a public servant toil more earnestly and disinterestedly for the attainment of the great purpose of his office. He had to struggle on, with little encouragement, in the face of difficulties which only a brave and devoted nature could have faced. First of all, his official position was for many years a most precarious one. Though the Legislature, in a fit of patriotic fervour, had sanctioned the equipment of a geological survey, and had voted a slender sum for its maintenance, yet it soon naturally enough began to ask what value it received for the money thus expended. The Ministers of the day could not always satisfy utilitarian legislators, and indeed Ministers themselves were not infrequently lukewarm friends if not avowed enemies to the young Survey. Mr. Logan's tact in steering his bark through all these obstacles, and finally gaining the haven of popularity both for it and for himself, is above all praise. Yet this was done without the surrender of any of the thoroughly scientific spirit in which his labours were at first conceived. He and his associates worked steadily as true men of science, but they never forgot that in a young country, with resources not only undeveloped but unknown, the exploration of its mineral wealth was a matter of primary importance. Hence year by year, in the reports of progress presented to the Canadian Parliament, he was able to give fresh information regarding commercially important rocks and minerals, while at the same time putting forward facts of the highest interest to students of geology all over the world. It is in these official reports that the chief work of Sir William Logan's life is embodied, including of course the admirable maps on which the field-work has been published.

But his difficulties lay not only in official quarters. He had to go forth into the forest and ascend unvisited rivers without a track or a map. He had to make his own map as he went along, camping out with Indian attendants for months together, and forcing his way as a true pioneer of civilisation, through solitudes which in a few years later were to become scenes of active industry. Through all such hardships he carried a devotion which not only brought him cheerily to the end of them, but inspired his officers with much of his own energy in the common cause. And not his own small staff merely, but farmers, country doctors, and settlers of all kinds whom he enlisted into his service for such work as he found them able and willing to undertake. He used, for instance, to describe graphically and with much quiet humour how in this way he got a number of utterly unscientific colonists to aid in tracing a band of limestone through a district where no rock could be seen for the covering of soil and drift. He provided them each with a long iron-pointed stick and an acid-bottle, and instructed them to thrust the stick well down through the soil till they struck it against the solid rock underneath. Thereupon, pulling it out, they were to apply a drop of acid to the bruised grains of stone adhering to the point of the stick. If they saw a brisk effervescence, they were to mark the place as lying on limestone.

The organisation of the Canadian Geological Survey was admirably adapted for the work to be done, and shows Sir William's skill as an administrator. Directing the whole operations himself, working personally in the field at original observation as well as visiting and superintending the field-work of his staff, he had to get the utmost amount of work done for the smallest amount of money. He secured some excellent assistants in the field-work, whose names have long been familiar to geologists—Alexander Murray, now ably directing the Newfoundland Survey, James Richardson, and, in later years, Robert Bell and others. He early saw that the field-work required to be aided in two important directions—mineralogical and chemical analysis, and palæontological determination. Accordingly, he obtained for the former subject the services of Dr. Sterry Hunt, whose reports on Canadian rocks and minerals and contributions to chemical geology have since become so well known; while for the latter he fortunately found and retained Mr. Billings, who has done such good work among the invertebrate fauna of the older palæozoic rocks of British North America. Ever ready himself to give information and assistance, he everywhere solicited and obtained it from others for the advancement of the Survey.

Of the benefits which the Survey has conferred on Canada, perhaps the best proof is furnished by the firm footing and comparatively liberal equipment which it has now obtained from the Provincial Legislature. The Survey has opened up in a systematic and trustworthy way the mineral structure and resources of the colony. It has formed a museum and laboratory in which the minerals, rocks, and fossils of the country are examined and illustrated with special reference to the industrial development of the country. It has been the means of creating reliable topographical maps over wide regions which had not previously been depicted on any map.

It would take longer to enumerate the many services which Sir William Logan's Survey has rendered to Geology. Foremost among them we should probably place the great additions which it has made to our knowledge of the stratigraphy of the older formations. The existence of the vast Laurentian system with its twofold set of rocks and its Eozoon limestone was a fact first made known by Logan and his associates. The position of the Huronian system was likewise recognised and its name given by them. The northward development of the well-subdivided North American Silurian series with its abundant and characteristic fauna has been most diligently followed out and described by the same band of observers. They have, moreover, given the Survey a European reputation for their chemical and mineralogical work, and for their contributions to our knowledge of some of the older forms of palæozoic life.

These various and admirable labours were in large measure inspired by the genial enthusiasm of the director. The official narrative of them contains the record of the main work of his life. During more than a quarter of a century, while constantly engaged in active and successful exploration, he hardly ever published any papers except in the parliamentary blue-book, in which his annual report was ordered to appear. He seldom came before scientific societies with an account of his discoveries, but cheerfully accepted the more restricted circulation and flimsy appearance of the Yearly Report to the Government. The generalised summary which he published in 1863, in a thick volume, on the progress of the Survey during the first twenty years of its existence, contains the gist of his work, as well as a luminous account of all that was then known of the geology and mineral wealth of the province.

In the year 1856, after his successful representation of the mineral productions of Canada at the Paris Exhibition of 1855, Sir William Logan received the honour of knighthood in recognition of his long and unwearied exertions in the task which he had undertaken. He met with abundant tokens of appreciation from scientific societies both in Europe and in America, and he had the great gratification of seeing that this widespread testimony to the value of his labours and those of his associates was not without its influence upon society in Canada. By impressing his fellow-countrymen with the idea that after all there might be something useful and even to be proud of in their Geological Survey, it probably in no small measure helped to secure the position of the Survey as an institution deserving of support and extension.

In the year 1869 Sir William, finding at last that the duties of his office were becoming too heavy for his advancing years and failing health, resigned his appointment, and was succeeded by Mr. A. R. C. Selwyn, who had served in the Geological Survey of Great Britain, and afterwards directed the Survey of Victoria. His unabated interest in his favourite science, however, was shown by his donation of $20,000 towards the endowment of the Chair of Geology in M'Gill College, Montreal.

Sir William's collected papers and reports would make several stout volumes. They were always written clearly and for the sole purpose of telling what he had seen and believed or inferred. They did not in the least address themselves to the general or popular audience. Indeed, he used to confess himself wholly at sea when called upon

to address such an audience, either with the pen or the voice, and gave as an illustration a great meeting convened by his fellow-citizens to welcome him back to Canada after he had been knighted. He was, of course, expected to say something of himself and of his visit to Europe. He tried his best, he said, but soon grasping a long pointer, turned round to some maps and diagrams illustrative of the geology of Canada, and only recovered his peace of mind and command of language when he found himself once more among Laurentian, Huronian, gneiss, limestone, and the rest of his beloved rocks. Nevertheless, he kept copious journals of his various expeditions, and illustrated them with most admirable pen-and-ink sketches. A selection from these could hardly fail to be of great interest, both in relation to the man himself and to the way in which geology has to be carried on amid the wild life of the backwoods.

By those who were privileged with his friendship, Sir William Logan will be affectionately remembered as a frank, earnest, simple-hearted man, ever gentle and helpful, enthusiastically devoted to his profession, and never happier than when discussing geological questions in a *tête-à-tête*, full of quiet humour, too, and showing by many a playful sally in the midst of his more serious talk, the geniality and brightness of his sunny nature. Peace to his memory! He has done a great work in his time, and has left a name and an example to be cherished among the honoured possessions of geology.

ARCH. GEIKIE

TREVANDRUM MAGNETIC OBSERVATIONS

Observations of Magnetic Declination made at Trevandrum and Agustia Malley in the Observatories of his Highness the Maharajah of Travancore, G.C.S.I., in the Years 1852 *to* 1869. Vol. i. Discussed and edited by John Allan Broun, F.R.S., late Director of the Observatories. (London: Henry S. King and Co.)

WE have heard a great deal lately about the native rulers of India, and the worst features of one of them have been brought very prominently before us; but it is a pleasing reflection that they are not all like the potentate of Baroda, while some of them might even read a lesson to the paramount power. Let us hear what Mr. J. Allan Broun, a magnetician of great eminence, has to say of the late ruler of Travancore.

"The Trevandrum Observatory," he tells us, "owed its origin in 1836 to the enlightened views of his Highness Rama Vurmah, the reigning Rajah of Travancore, and to the encouragement given to them by the late General Stuart Fraser, then representing the British Government at Trevandrum. His Highness, desirous that his country should partake with European nations in scientific investigations, sanctioned the construction of an observatory, named Mr. Caldecott its director, and gave him power to furnish it with the best instruments to be obtained in Europe."

The peculiar position of Trevandrum, not far from the magnetic equator, induced Mr. Caldecott, with the Rajah's permission, to procure from Europe a complete equipment of the best instruments for magnetic and meteorological observations, and to build a magnetic observatory, which was completed in 1841.

Mr. Caldecott died at Trevandrum in 1849, and the observatory was in January 1852 placed under the direction of Mr. John Allan Broun, who had previously directed with well-known success the observatory of Sir T. Brisbane at Makerstoun, in Scotland.

Mr. Broun began his office with the conception of an interesting and important problem in terrestrial magnetism, which he was determined as far as possible to work out. This would render it necessary that the observations should not be limited to a single station. He wished, among other things, to determine how far the physical constants of terrestrial magnetism and their various changes depend on differences of height, of latitude, and of longitude.

The Agustia Malley, the highest mountain in the neighbourhood, was chosen as affording the best means for determining the effect of height, and accordingly Mr. Broun resolved to erect an affiliated observatory on this nearly inaccessible rocky peak, surrounded by forests, the inhabitants of which were elephants and tigers. These and all other difficulties connected with this formidable undertaking were, however, completely vanquished, and the Agustia Observatory was completed in 1855.

We learn from Mr. Broun that his labours were not entirely confined to these two observatories. "Other observations," he tells us, especially of magnetic declination, were made simultaneously "during short periods at different stations in Travancore, as nearly as possible on the magnetic equator, 90 miles north of Trevandrum, and also 40 miles to the south. Observations connected with meteorological questions were also made simultaneously to the east and west, and about 5,000 feet below the Agustia peak, on the peak itself, and at Trevandrum; while on one occasion hourly observations were made during a month at five different stations, varying gradually in height from the Trevandrum Observatory (200 feet) to 6,200 feet above the sea-level, in which fifteen observers were employed."

In this first volume Mr. Broun has confined himself to the magnetic declination, and one of the chief objects sought has been to determine every possible action of the sun and moon upon the magnetic needle. The observations extend from 1852 to 1870, and embrace in all nearly *three hundred and forty thousand readings*.

A considerable portion of the introduction is devoted to the discussion of a question which has, we think, been somewhat too much overlooked. When a magnet is suspended by a thread and enclosed in an appropriate box, it does not necessarily follow that all its movements are due to magnetic causes, for changes in temperature and humidity may affect the zero of torsion of the thread, and thus cause slight changes in the position of the suspended magnet. It is perhaps unlikely that such changes could seriously affect the character of the daily variation, but it has been thought that they might perceptibly affect the annual variation, since in this case the magnetic change is comparatively small, while the range of temperature and humidity is generally great.

Mr. Broun overcame this source of error by observations of an unmagnetic brass bar suspended in the same way as the magnet, which thus afforded him the means of estimating, and hence eliminating, the error due to these causes.

Besides all this, several declinometers were used and

compared together, and the result of all these comparisons tends to impress the reader with the fact that we have in this volume a series of observations of the magnetic declination of a thoroughly accurate and trustworthy nature.

The following passage from Mr. Broun's magnetic diary may be quoted as exhibiting the sources of error to which magneticians are exposed, as well as the care bestowed in avoiding them—

"1855, Dec. 4d. 9h. A sudden vibration of Grubb's magnet through thirty scale divisions was observed, and the difference of Adie's and Grubb's instruments, which had previously been − 0'·05, became suddenly + 3'·50. It was supposed that either the suspension thread was breaking, or that a spider had got within the box.

"Dec. 4d. 22h. The boxes were removed, and an exceedingly small spider was discovered and removed. This was the only occasion in which a spider succeeded in entering Grubb's declinometer boxes between 1852 and 1870. Every care was taken when the boxes were removed, before replacing them, to hold them for some time over the flame of a lamp, so that spiders, even invisible to the naked eye, must have been dislodged or destroyed."

It remains now to give our readers a summary of the most important results obtained by Mr. Broun from the reduction of his observations.

In the first place, the *secular variation* is found to be irregular, but the observations seem to indicate that after a certain interval the acceleration or retardation of the secular movement has equal values. *This interval is estimated at* 10·5 *years.* In order to find the *annual period*, the variations which form the secular and decennial inequalities have been eliminated. The observations then indicate a twofold inequality, one of which corresponds to a single oscillation in a year, with a minimum in March or April, and a maximum in September or October, while the other represents a double or semi-annual oscillation with maxima in March and September.

Mr. Broun was also led to suspect a *period of forty-four months*, which was repeated four times successively in his observations, although no cause is known which could produce an inequality of this duration.

The next inequality noticed is *the twenty-six day period*, which Mr. Broun is inclined to attribute to solar action with more confidence than the longer period of ten or eleven years. Our readers will remember that the period was re-discovered by Dr. Hornstein, director of the Prague Observatory. Mr. Broun thinks that there are traces of a double oscillation of the twenty-six day period.

Coming next to the important *solar diurnal variation*, the chief features of which are tolerably well known, Mr. Broun finds this to consist of one marked maximum and one marked minimum of easterly declination in each month of the year, and of one or more secondary maxima and minima.

The principal maximum occurs in the six months of April to September at about 7 A.M., and the principal minimum about twenty minutes past noon in the same months. Nearly the inverse of this happens in the four months of November to February. The results obtained by Mr. Broun appear to him to indicate the action of opposite forces belonging to the two hemispheres, which mainly destroy each other in March and October at Trevandrum, but one of which is preponderant in the other months of the year; and of these forces he remarks that those of the northern hemisphere seem to have a greater effect on the variations of the whole globe than those of the southern hemisphere.

The daily range was a minimum in 1856 and a maximum in 1860. It is a minimum in March and October, and a maximum in August and December.

In considering the *lunar diurnal variation*, Mr. Broun begins by showing that the results relating to the variation to be obtained by him are really due to the lunar action, and not to any portion of solar perturbation remaining uneliminated.

The following very singular results have been obtained :—

1. The mean lunar diurnal variation consists of a double maximum and minimum of easterly declination in each month of the year.

2. In December and January the maxima occur near the times of the moon's passages of the upper and lower meridians; while in June they happen six hours later, the minima of easterly declinations thus occurring near the times of the two passages of the meridian.

3. The mean of the ranges of the lunar diurnal variation shows (like the solar diurnal range) a minimum in 1856 and a maximum in 1860.

4. The action of the moon on the declination needle is greater in every month of the year during the day than during the night.

5. There appears to be a remarkable change in the lunar action connected with the rising and setting of the sun, especially with the former.

We now come to a part of the reductions where we feel compelled to differ from the eminent magnetician as to what may be termed the scientific policy which he has pursued. We allude to the question of disturbances.

There can, of course, be no doubt that a strictly mathematical discussion of a series of observations will indicate the various periods of action of the influential forces. We know that this method served to indicate many important astronomical periods long before the mechanical nature of the astronomical forces was recognised.

We might, for instance, take a body of meteorological observations and treat them in a strictly mathematical manner, and we should no doubt be led to a yearly and to a daily period, even if we were not acquainted with the existence of the sun. But who would pursue this method? We take advantage of the knowledge derived from other sources of the exact length of these two periods to begin with, and do not think of endeavouring to obtain these by means of the observations themselves.

Furthermore, in meteorology, with the general consent of all engaged in it, we have gone even further than this. There is unquestionably a distinct daily and yearly fluctuation of the meteorological elements brought about by the sun, but besides this there are other phenomena ultimately due to the sun, though not in the same way, which meteorologists have agreed to consider apart by themselves.

We allude to cyclones, which, when examined separately, are found to obey very different laws from those which regulate ordinary atmospheric changes. Thus these laws have been discovered by agreeing to separate certain observations which were unmistakably abnormal,

and to discuss those by themselves, and the result has been the most interesting and important discovery of the law of storms. And if it be asked what right meteorologists had to separate a body of disturbed observations, the reply will obviously be that they are justified by their success. Deny the right, and a cyclone becomes an altogether false and illegitimate scientific conception.

Now, a large and increasing number of magneticians are of opinion that the phenomena of terrestrial magnetism can bear a similar treatment. They believe that the sun has a daily and yearly influence on the magnetism of the earth just as it has upon its meteorology, and they also believe that it is the cause—the indirect cause, it may be—of an abnormal magnetic influence, just as in meteorology it is the indirect cause of the cyclone. Some even go so far as to say that these two abnormal influences, the one in magnetism, the other in meteorology, are intimately connected together. This assertion, however, is not now the point in question. The point is that we have in magnetism certain abnormal disturbances which may be compared to abnormal meteorological disturbances. Now, it is held by Sir E. Sabine and those who share his views, that it is expedient to separate out these disturbed magnetical observations, just as we separate out the meteorology of a cyclone. This school assert that we may thus arrive at a series of phenomena obeying very different laws from those of the undisturbed observations, and that we are therefore justified in making the separation, inasmuch as we are thereby led to a clearer knowledge of the various ways in which the sun affects the magnetism of the earth. And they insist very strongly upon the point that both these magnetic actions of the sun have diurnal and annual variations different from one another, so that if treated together we obtain a result much more complex than if they be treated separately.

We have little doubt of the policy of this method of treatment, and we cannot, therefore, but regard it as a misfortune that Mr. Broun has not unmistakably adopted it. He has, however, given us all the individual observations, so that, if it be thought desirable, those magneticians who advocate a somewhat different method of reduction may make it for themselves. We need only add, in conclusion, that the appendices will be found to be very interesting reading, and that all who are interested in terrestrial physics must look with great interest to that magnificent series of researches of which the volume before us forms the first instalment. B. STEWART

OUR BOOK SHELF

Chapters on Sound, for Beginners. By C. A. Martineau. (London: The Sunday School Association; Manchester: Johnson and Rawson, 1875.)

WE have read this little book with great pleasure. Its object, the author tells us, is to teach a few of the simpler facts in acoustics in such a way that the learner shall not be deterred by unnecessary difficulties, either in the use of technical language or in having to provide expensive apparatus. Most successfully has the author attained the end he had in view. It is just what a child's book on science should be. Written in a simple attractive manner, without any silly childishness, it conveys a great deal of information, and that in the best kind of way. For the learner, by a series of simple experiments, is made to lay firmly the groundwork of his knowledge on this subject. All the apparatus the author requires is a toy fiddle, one or two small tuning-forks, a couple of finger-glasses, a clamp, a square and a round piece of glass, a gimlet, a tall jar, silk thread, and some solitaire balls. With such homely instruments really good elementary teaching is given. The chapter on strings made to vibrate in time with tuning-forks is capitally done, and will give the learner more knowledge than he could gain from many a pretentious text-book. We should like to suggest to the author a few additions to his simple experiments, but in the limits of this notice we cannot do more than direct his attention to the Instructions in practical physics given to the science teachers at South Kensington, and printed for their use by the Science and Art Department. There is of course nothing new in the way of experimental illustration in these chapters on sound; it is the good use the author has made of what has been done by others that is the merit of this little book. We gladly recommend it to all girls and boys who will honestly go through what is to be done as well as what is to be read.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

On the Temperature of the Human Body during Mountain Climbing

THE account of Dr. Forel's laborious and carefully conducted observations on the temperature of the body during mountain climbing, given in NATURE, vol. xii. p. 132, has recalled to mind the results of a few observations which I made shortly after the publication of Dr. Lortet's and Dr. Marcet's experiments. As my results are in the main confirmatory of those of Dr. Forel, they may not be without interest as a contribution to what, until the appearance of Dr. Forel's memoirs, was regarded as the heterodox side of the question.

Before joining the party of observers sent out to Sicily to see the solar eclipse of 1870, I provided myself with a set of delicate clinical thermometers with a view of repeating the observations of Drs. Marcet and Lortet, should any opportunity occur of getting up Etna during our stay in the island. On Christmas-day a number of us attempted to make our way up the mountain, and with the aid of Mr. Fryer I made a number of observations of body-temperature on myself during the ascent. The temperature of the mouth was taken, as in the observations of Marcet and Lortet. The thermometer employed was carefully selected so as to get the maximum amount of displacement in the column for a thermal disturbance with a minimum bulb-capacity. As regards sensitiveness, it left little to be desired. Some weeks before the start a number of preliminary observations were made with the view of ascertaining the best manner of placing the thermometer and of determining the length of time required for the column to attain a position of rest. By repeated trials it was found that fully five minutes were needed after placing the thermometer in position before the level of the mercury became approximately constant, both during repose and after a rapid run. Any subsequent variation seldom exceeded $\frac{1}{20}$ of a degree F. The following readings taken from among a number of similar observations will serve to show the extent of the changes from minute to minute after placing the thermometer *in situ*:—Time, 7·30 P.M.; condition, rest. After first minute: Temp., 96°·4; second, 97°·9; third, 98°·4; fourth, 98°·5; fifth, 98°·5. That there is nothing in the rate of change peculiar to the individual is evident from the results of a similar series made at the same time upon another person: first minute, 96°·4; second, 97°·0; third, 97·5; fourth, 97°·8; fifth, 97°·8.

On the day of the attempted ascent we set out from Catania at 5·30 A.M., and drove to Zaffarana. Mouth-temperature before starting, 98°·4. In the carriage, 98°·3; time, 9h. 10m.; pulse, 78. At Zaffarana, 98°·4; pulse, 83. As Zaffarana lies at a considerable elevation above the sea-level, the observations so far serve to confirm Dr. Marcet's statement that the rarefaction of the air is without influence on the temperature of the body. After a stiff walk of thirty-five minutes, during which the

aneroid fell 0·49 inch, the temperature was again found to be 98°·3; pulse, 116; time, 10h. 42m. Twenty-three minutes later, after rapid walking (barometer 0·48 inch lower than previous reading) the observations were: First minute, 96°·3; second, 97°·4; third, 97°·6; fourth, 97°·7; fifth, 97°·8; pulse, 116. At 12h. 4m., after continuous walking at a good speed, the observations were: First minute, 94°·2; second, 96°·2; third, 97°·4; fourth, 97°·8; fifth, 98°·1; pulse, 128. The pace was now quickened almost to exhaustion, and at 2·30 P.M., when greatly fatigued, the observations were: First minute, 93°·9; second, 95°·6; third, 96°·8; fourth, 97°·4; fifth, 98°·0; pulse, 90. These last observations were made with some difficulty, and under such circumstances that I am disposed to attach less weight to them than to the former readings. My exhaustion was doubtless partly due to hunger, for I purposely fasted in order to test the correctness of Lortet's statement that the fall in temperature is specially marked during an ascent made when hungry.

These observations were all I could obtain, as I was too much fatigued to carry on the work. They are scarcely numerous enough to enable any very definite conclusions to be drawn; but so far as they go, they certainly are not confirmatory of the conclusions arrived at by Drs. Marcet and Lortet; they at least prove that if any decrement does occur during climbing, it is never so great as 8° (Lortet), or even as much as 3° (Marcet).

It may be thought that the low readings obtained in the later observations on first placing the thermometer in the mouth, are indicative of a decrease in body-temperature. It must be borne in mind, however, that, especially in the later observations, we were facing a keen wind sweeping down a mountain partially covered with snow; it is perfectly obvious from this cause that the first minute's observations can afford no reliable indication of the temperature of the mouth, or otherwise the body must recover its normal temperature with a rapidity which would be perfectly extraordinary. From repeated trials made on myself and others, I have come to the conclusion that observations of the temperature of the mouth taken even after the end of the second minute give no trustworthy indication of the temperature of the body; such indications are of no value even as comparative measurements.

As it seems quite certain that any variation which may occur is a matter of tenths and not of whole degrees, it may be well to point out a source of error in the method of observation which seems to have escaped the attention of observers hitherto, but which in any case is too considerable to be neglected, although it would specially affect the results obtained at high altitudes. In taking the temperature of the mouth on a mountain, surrounded by a rapidly moving atmosphere at a temperature often but little higher than that of melting snow, it is obvious that the mean temperature of the mercurial column must be considerably lower than that of the mouth, since the greater portion of the stem is in the cold air. The correction to be added to the readings is readily calculated if we know the length of the exposed column, its mean temperature, and the apparent expansion of mercury in glass. If we suppose the length of the exposed column in the observation taken at 2.30 P.M. to be forty times the length of a degree, and its mean temperature that of melting snow, the correction to be added to the last reading would amount to a quarter of a degree.

The whole subject unquestionably merits reinvestigation. A much larger number of observations is needed; these should be made under similar circumstances on different persons, for it may well happen that the bodily idiosyncrasy of the individual may affect the result. Possibly some Alpine party may undertake the solution of the problem during the present season. It is doubtless not so simple as it may at first sight appear. From my experience during the ascent of Etna, and from what I have been able to glean of the manner in which other observations have been made, it seems clear that the conditions necessary to obtain perfectly comparable results have yet to be determined. Should any variation be observed, either in the direction observed by Drs. Marcet and Lortet or in that indicated by the experiments of Dr. Forel, it would be specially interesting to determine how quickly the human body recovered its normal temperature on resting.

T. E. THORPE

Arctic Marine Vegetation

IN NATURE, vol. xii. p. 55, an interesting article on the Arctic marine vegetation, quotes Ruprecht (with doubt as to his accuracy) in regard to an asserted absence of Algæ in Behring Sea and the waters north of it.

That doubt is well founded, as I can testify, having been engaged during a large part of ten years in explorations of that region. The line of the Aleutian Islands from east to west is girt with seaweeds, which are quite as abundant on the north as on the south side of this archipelago. If Ruprecht, however, referred to the waters still further north, he is equally in error. Unfortunately I am not possessed of much more botanical knowledge than comes from collecting for my botanical friends, and to them I must leave the task of enumerating the species, but perhaps a few remarks on the general distribution of the Algæ of this region may not be without interest. It is noteworthy that fine and beautiful seaweeds, such as are used for ornamental albums, are comparatively quite rare on the whole coast, from the Vancouver Archipelago north and west. Rhodosperms are particularly scarce in individuals, though how far this may be true of species I am not competent to say. Chlorosperms are confined to a very small number of forms, also rare as individuals. The great mass of the algoid vegetation of this region is made up of Melanospermæ.

Some forms which I believe are closely related to if not identical with *Fucus vesiculosus*, are found in masses on the rocky shores of Behring Sea, from the Aleutian Islands north to Behring Strait, and I do not know how far beyond.

The distribution of the Algæ seems to be largely dependent upon the character of the rocks. Basaltic shores are least rich and afford few forms, except what I have called *F. vesiculosus*, and species of *Agarum*. Granitoid rocks and Tertiary sandstones and conglomerates always afford at least a few forms of red and green seaweeds, while on the metamorphic slates and porphyritic rocks, which make up the greater part of the Aleutian chain, the *Nereocystis*, *Laminaria*, *Nullipores*, and *Agarum* seem to find their most congenial home. The character of Behring Sea is unfavourable for the growth of seaweeds. Much of the eastern plateau is of soft sticky mud or fine clean black volcanic sand, affording no hold for Algæ. But wherever there are rocks Algæ may be found, though the more delicate kinds are always rare. Jointed and incrusting stony Algæ are abundant on most of the Aleutians, and I have noticed them also at the Pribiloff group, Nunivak, Norton Sound, and Plover Bay in East Siberia, though less common northward.

The "bull-head kelp" (Nereocystis?) is excessively abundant in the Aleutians, and extends north to Nunivak and the Pribiloff Islands. There is a patch of twenty-five square miles in extent, north-east of St. George Island, on a shoal in the open sea. I do not recollect its occurrence further north than Nunivak. *Laminaria* extends to the Straits, and possibly north of them, with *Agarum*, the two most abundant seaweeds of Behring Sea. *F. vesiculosus* everywhere where there are rocks; also a flat, leathery, thick-fronded alga with short stalks, which the sailors call "devil's aprons." These have the edges variously cut or indented, though some forms are oval, with two thickened marginal bands extending outward from the stalk. In Norton Sound, in 1865–66 and 1867, I obtained what seemed to me to be at least fifteen or twenty species of algæ, which included something that I could not distinguish from the "Iceland moss" of the coasts of New England, and which was not found further south. In many places where the bottom was unfavourable for algæ I have found dead shells and living crustacea entirely hidden under a growth of red and green algæ, which, without exercising great care, would often have led to the rejection of valuable specimens of invertebrates from the dredge, from their being taken for mere bundles of seaweed.

I may also mention that in the hot springs (110°–180° F.) which exist on the peninsula of Alaska and many of the islands, there is invariably a leathery brown algoid, covering the bottom of the basins in which the springs occur. *Nostoc* also flourishes in the fresh waters emptying into Norton Sound. I have many times noticed the *F. vesiculosus* apparently flourishing in lagoons where the water was barely brackish to the taste, and to which the sea had no access except in extraordinary storms such as might occur once or twice in a year.

Much of the above may be without interest to the scientific botanist; I leave it to your judgment what to reject, but I think that there is no further necessity for disproving the error into which Ruprecht has in some way been led; certainly, if he had himself walked the beaches of Behring Sea, where any rocks exist, he could not have come to such a conclusion.

South American Earthquakes

On the 18th May, that is, the same day that, if the telegraphic news be correct, the cities of Cucuta, Santiago, and others were destroyed by an earthquake, a distinct and prolonged shock, preceded and accompanied by a loud rumbling noise, awoke the greater number of the inhabitants of this place, about a quarter of an hour before midnight. The direction of the phenomenon was thought by some who heard and felt it to be from east to west; but this opinion was, I have reason to believe, inaccurate.

Not knowing as yet the exact time at which the Columbian disaster took place, I am unable to calculate the rate at which the shock, connected with, one can hardly doubt, the great earthquake above alluded to, may have travelled the long distance that separates St. Thomas from Cucuta. Fuller details may subsequently, I hope, help to elucidate the matter.

It is worthy of note that whereas before the 18th May an unusually long period had elapsed during which no subterraneous vibrations had been felt in this island, there have occurred since that date several slight shocks at various hours of the day and night, with a frequency above the average.

St. Thomas, West Indies W. G. Palgrave

Glacier and other Ice

The reviewer of Croll's "Climate and Time" in Nature of the 24th June (p. 144) says: "What is there in this (Mr. Croll's) theory to distinguish a glacier from a common piece of ice? which on this principle ought to flatten out and not retain its shape as it does."

I believe that, independently of any theory of the cause of glacier motion, there is no physical difference whatever between glacier and other ice. The greater mobility of a glacier is merely due to its greater size and weight; just as water in a river-bed flows with very little friction, under a pressure that would not make it flow at all in a capillary tube. The plasticity of ice may however be shown on a small scale. I have read somewhere that a slab of ice supported only on its two ends will gradually bend down in the middle: and I have seen Prof. James Thomson at the Belfast Museum illustrate a lecture by moulding a few lumps of ice by pressure into the shape of a cup.

I am not writing in defence of Mr. Croll's theory of glacier motion. I believe the best explanation of those physical properties of ice on which glacier-motion depends is that given by Prof. James Thomson. I know Mr. Croll's theory only from your review, and I do not know how far it agrees with Prof. Thomson's. Joseph John Murphy

Old Forge, Dunmurry, Co. Antrim, June 26

The House-fly

I am disappointed to find that no one has answered "Harrovian's" query in vol. xii. p. 126, as to the mortality amongst the house-fly, and the yellow powder which covered the carcase. I have noticed myself that house-flies often die in numerous company. I had an idea that it was owing to the temperature falling to its benumbing point, until I found the same thing happening while the thermometer was particularly high. Then I thought that all these dead flies might belong to the same brood, and having lived under almost exactly the same circumstances, their threads of life were spun out at almost exactly the same time. This new theory, again, did not stand examination well under the microscope. But the result of my experiment differed slightly from that of "Harrovian." At least I find I entered in my notes, "the body covered with white eruption, apparently a disease of the skin."

OUR ASTRONOMICAL COLUMN

An Ancient "Uranometria."—We have received a very interesting work, published by Dr. Schjellerup, of the Observatory of Copenhagen, under the auspices of the Imperial Academy of Sciences of St. Petersburg. It contains a description of the constellations, with the star magnitudes, composed in the middle of the tenth century by the Persian astronomer, Abd-al-Rahman al-Sûfi, and is a literal translation of two Arabic manuscripts preserved in the Royal and Imperial libraries of Copenhagen and St. Petersburg. A more particular account of the valuable addition which Dr. Schjellerup has made to the literature of astronomy will be given in this column next week. Meanwhile, we may just note one curious statement made by the Persian astronomer with reference to the well-known variable star Algol, viz., that at the time of his observations the star was *reddish*—a characteristic applied also to Antares, Aldebaran, α Hydræ, and a few other stars, which are also reddish in our own day; but at present there is no tinge of colour about Algol, which may be fairly described as a white star, and if there be one of its class more than another in which the periodical fluctuation of light can with much appearance of probability be attributed to the intervention of a revolving attendant, passing regularly in our line of sight, it is to this star that we might point in illustration. Its former ruddy light, however, rather necessitates a different explanation, and one which, notwithstanding the comparative regularity of its changes, may perhaps assimilate it to the more numerous class of variable stars.

The "Black Saturday" Eclipse, 1598, March 7.—This eclipse, which was visible in its total phase in Scotland, like that of 1652, April 8, noticed in this column last week, was remembered long afterwards in that country, the day of its occurrence being called "Black Saturday." The elements were very approximately as follows:—

Conjunction in R.A. 1598, March 6, at 23h. 1m. 38s. G.M.T.

	°	′	″	
R.A.	347	44	8	
Moon's hourly motion in R.A.		32	9	
Sun's " "		2	18	
Moon's declination	4	16	1	S.
Sun's "	5	16	33	S.
Moon's hourly motion in Decl.		17	8	N.
Sun's " "		0	59	N.
Moon's horizontal parallax		59	51	
Sun's "			9	
Moon's true semidiameter		16	19	
Sun's "		16	5	

The sidereal time at Greenwich noon on March 7 was 22h. 59m. 34s., the equation of time 11m. 33s. subtractive from mean time, and the middle of general eclipse at 22h. 10m. 29s.

Hence the following points upon the central track of the shadow:—

Long.	6° 21′ W.,	Lat.	51° 15′ N.	Long.	3° 14′ W.,	Lat.	55° 48′ N.
"	4 17	"	54 12	"	1 55 E.	"	64 29
"	3 45	"	54 59	"	5 27 E.	"	71 37

The semi-diameter of the belt of totality appears to have been about forty-five miles only. This belt included Edinburgh, where the total eclipse commenced about 10h. 15m. 36s. A.M. on March 7, local mean time, and continued 1m. 29s. with the sun at an altitude of 26°. At Douglas, Isle of Man, the eclipse was also total for about the same interval, the sun disappearing at 10h. 6m. 43s. A.M. local time according to the above elements.

The date for this eclipse is given for *new style*, as was also that for the eclipse of 1652.

While referring to this subject we may mention that Dr. Celoria, of the Observatory of Milan, has calculated the circumstances of the total solar eclipse of 1239, June 3, from the tables of Hansen—with Leverrier for sun. Prof. Schiaparelli had collected together a large number of notices of the totality of this eclipse in its passage across Italy, his authorities being chiefly found in the great work of Muratori. It appears to have been total (if we may assume totality from the visibility of stars and the night-like appearance of nature) at Monpellieri, Mirabeau (where Zach found an inscription referring to the phenomenon), Digne, Alessandria, Genoa, Piacenza, Parma, Lucca, Modena, Florence, Siena, Arezzo, Este, Ravenna, Lesina on the Adriatic, &c.; but Hansen's tables, accord-

ing to the calculations of Celoria, do not include the greater number of places within the belt of totality. It may be remembered that a calculation of the eclipse which occurred only two years later (1241 October), published by Hansen in the Transactions of the Saxon Society of Sciences, gave a total eclipse both at Erfurt and Stade near Bremen, where it is recorded to have been so observed, and hence his tables were considered satisfactory. Both eclipses may deserve further examination.

D'ARREST'S COMET.—This comet appears now to make a very close approach to the orbit of the planet Jupiter, from which circumstance it is possible that in some forty-five years from this time its elements may be entirely changed. Considerable perturbations from the attraction of this planet took place between the latter part of the year 1857 and the next period of the comet's visibility, so that by Leveau's calculations for that epoch the time of revolution had been increased sixty-eight days, the inclination diminished more than two degrees, with very material changes in the other elements. If we adopt the orbit found by Leveau for the last appearance, we have the following distances of the comet from the orbit of Jupiter at different points of heliocentric ecliptical longitude—equinox of 1872:—

In 139°	1′	distance	0·411	...Aphelion
146	28	,,	0·292	...Ascending Node
150	0	,,	0·189	
152	0	,,	0·098	
153	0	,,	0·085	

In longitude 153° 10′, which is about the point of nearest approach, the distance between the two orbits is only 0·0841. At this point the comet's radius-vector is 5·4254, with latitude 1° 52′ N., and it is passed 873 days or 2·39 years before the arrival at perihelion. Without very sensible perturbations in the mean time, the comet and planet would encounter each other at the latter end of the year 1920, when, as noted above, an entire change of orbit might take place.

THE MINOR PLANETS.—Inquiries are occasionally received for the fullest catalogue of elements of the minor planets. Such readers as have occasion to refer to a pretty complete list, will find the latest and most authentic summary in the "Berliner Astronomisches Jahrbuch" for 1877, where the orbits of upwards of 130 of these planets are given, and in many cases from new and complete discussion. Indeed, the preparation of elements and ephemerides of the minor planets forms a speciality of the "Berliner Jahrbuch" under the superintendence of Prof. Tietjen. The labour and practical difficulty attending this work have now become very great, so much so as to require almost exclusive devotion to it of a body of computers, if accurate results for the guidance of observers are expected. Prof. Tietjen to a considerable extent ensures this. The elements are collected by him in each successive volume, the latest being found as stated above in that for 1877, published within the last few months.

ON THE PLAGIOGRAPH aliter THE SKEW PANTIGRAPH

I HAVE been led by the study of linkages to the conception of a new instrument, or rather a simple modification of an old and familiar one, the Pantigraph, by means of which a figure in the act of being magnified or reduced may at the same time be slewed round the centre of similitude. Some of the readers of NATURE, such possibly as my able and most ingenious friends, Messrs. George Cayley and Francis Galton, may be able to pronounce with authority how far the invention is new and whether it is likely to be found in any way useful in practice as applied to the art of the designer or engine turner. Already my invention of the Isagoniostat, or equal angle setter, which I shall take some other opportunity to communicate to this journal, has been deemed available in practice for working automatically the train of prisms of a spectroscope.

In Fig. 1, A O B C Q represents an ordinary pantigraph. O is the fixed point, P is the tracer, and Q the corresponding follower; then, as everybody knows, any curve traced out by P will be imitated by Q, and the two curves will be similarly situated in respect to O. The point of addition is the following:—

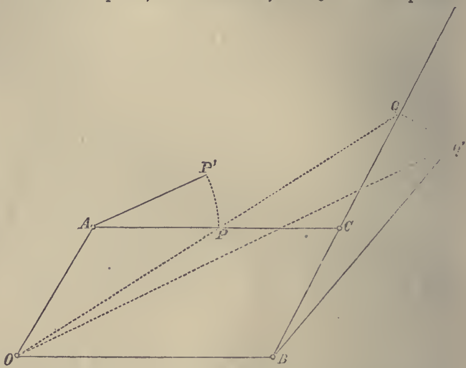

FIG. 1.

Let P be moved through any angle, P′ A P round A, and Q through *an equal angle* Q B Q′ in the *opposite* direction round B, and let P′ and Q′ be supposed to be in any manner rigidly connected with the bars A C, B C respectively. Then it admits of an easy proof that in whatever way the pointed parallelogram A O B C is deformed, O Q′ will bear to O P′ the constant ratio of A C to A P, and moreover the angle P′ O Q′ will always remain equal to the angles P′ A P, Q B Q.

It follows that whilst P′ is made to move upon any curve the follower Q′ will trace out a similar curve altered in magnitude, and at the same time turned round the first point O.

If, as in Fig. 2, we take A D equal to A C, B E equal to B C, and the angles C A D, C B E equal to each other, then the rays O D, O E will always remain equal and be inclined to each other at a constant angle. With this adjustment the instrument may be used to transfer a figure from one position in a sheet of drawing paper to any other position upon it, leaving its form and magnitude unaltered, but its position slewed round through any desired angle.

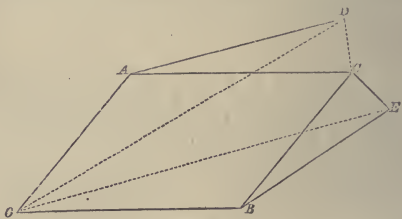

FIG. 2.

J. J. SYLVESTER

SCIENCE IN GERMANY

(From a German Correspondent.)

WHEN in 1819 Dulong and Petit measured the specific heats of some solid elements they found for each of the elements experimented upon, a very simple relation between its specific heat and its atomic weight; the product obtained by multiplying the specific heat

with the atomic weight gave a constant value, or, in other words, the atoms of all the elements experimented with have the same capacity for heat. The investigation of Regnault confirmed this law, showing that it is valid for most of the solid elements with tolerable exactness; but it should be remembered here that the specific heats of these elements must be determined at temperatures which are sufficiently below the melting points of the elements in question. Only carbon, boron, and silicon proved exceptions to this remarkably simple, natural law; for these three elements far smaller atomic heats were found. It was also found that the different allotropic modifications of these three elements possess quite different specific heats, and that none of these specific heats were in accordance with Dulong and Petit's law. Later on similar results were obtained by De la Rive and Marcet, Wüllner and Bettendorf. We must not forget to mention, for the sake of completeness, that with regard to the difference in the specific heats of the allotropic modifications of an element, Kopp has already, in 1864, stated his belief that all allotropic modifications of each element possess the same specific heat in all cases, and that the results of experiments which are contradictory to this view must be considered as caused either by a faulty method of observation or else by impurities in the substances used.

Herr Weber of Hohenheim has succeeded lately in proving the validity of Dulong-Petit's law, also for carbon, boron, and silicon; his experiments were made with Bunsen's ice-calorimeter. In order to heat the substances experimented upon to a series of temperatures below red heat, oil baths were used, and various temperatures between 0° and 300° C. were applied; in order to cool them, solid carbonic acid and a cold mixture, consisting of one part of snow and $\frac{1}{3}$ part of common salt, were employed. All these temperatures were read off directly from an ordinary air-thermometer. For higher temperatures (between 500° and 1000°) an indirect method was made use of, which allowed of the determination of the temperatures by means of the indications of the calorimeter. This indirect method is based on the correctness of Pouillet's determinations (published in 1836) of the quantity of heat which a certain unity of weight of platinum requires to become heated from temperature T_0 to T. (These determinations are given by Pouillet for the interval $T = 0°$ to $T = 1200°$ C.) The results which Herr Weber obtained may be stated as follows:—The specific heats of carbon, boron, and silicon increase regularly as the temperature rises, from the lowest obtainable degrees of temperatures upwards, and finally remain nearly constant after a certain degree has been reached. The nature of the function, which expresses the dependence of the specified heat γ from the temperature T, seems to be the same for all the three elements, and to possess the following formula:—

$$\gamma = A - \frac{B(1 + hT)}{e^{qT}}$$

where A, B, q and h express constant positive values, and $A > B$, $q > h$, and also T is the temperature counted upwards from the absolute zero.

The temperature from which the specific heat of carbon remains nearly constant is somewhere near 600° C., and it is immaterial whether the carbon is in the form of diamond or in that of graphite. From red heat upwards this element shows no greater variability in its specific heat than the other elements which follow Dulong-Petit's law. (At lower temperatures, however, for instance when the temperature rises from − 50° C. to + 600°, its specific heat increases sevenfold). The specific heats of graphite and diamond are perfectly identical above 600° C., if we neglect small differences, which do not exceed the numerical value of the specific heat by more than 0·5 to 2 per cent. The specific heats of graphite, of the dense amorphous coal, and of the porous charcoal, are within the interval from 0° to 225° C. perfectly identical from degree to degree. Thus all opaque modifications of carbon (the graphitic, dense and porous forms) have the same specific heat. We may say that below red heat, from a *thermal* point of view, there are only two different allotropic modifications of carbon, the transparent and the opaque one. The specific heats of these modifications differ all the more the lower their respective temperatures; if the latter rise, they approach each other steadily and become identical at about 600°. Above red heat there are no different allotropic modifications of carbon with regard to specific heat; from that point in the scale of temperature, where the *optical* difference of the two modifications of carbon ceases, the *thermal* difference ceases also. Kopp's view as quoted above is thus completely affirmed.

With regard to the specific heat of crystallised silicon, it approaches (analogous to the specific heat of carbon) as the temperature rises a nearly constant limit, which is reached at about 200°, after having passed through highly variable values. At that point of the scale of temperature the variability of the specific heat of silicon is no greater, than that of the metallic elements. With regard to the experiments with crystallised boron, it has been found that within the interval of temperature from − 80° to + 260° C. the specific of this element behaves in a manner which is perfectly analogous to the specific heats of opaque and transparent modifications of carbon. This great coincidence in the behaviour of the specfic heats of both elements justifies the supposition that also the specific heat of boron in a rising temperature approaches a nearly constant limit, and that this lies somewhere near a moderate red heat. Unfortunately, Herr Weber could not prove the correctness of this supposition by direct experiments through want of sufficient material.

The nearly constant final values, which are reached as the temperature rises by the specific heats of both carbon and crystallised silicon, were found to be, in round numbers—

For carbon	0·46
„ crystallised silicon	0·205

For crystallised boron, as we have said before, this final value could not be experimentally determined, but from the measurements that were made, and from the nature of the function which represents the specific heat of boron in its dependence upon temperature, we may conclude that this final value lies somewhere near 0·5. The atomic weights of the three elements, as found by the determination of their vapour densities, are—

Carbon	12
Silicon	28
Boron	11

The products of these figures when multiplied by the specific heats of these elements as mentioned above, give for their atomic heats the values—

5·5 ... ... 5·8 ... ... 5·5

i.e., values which closely correspond to the atomic heats of metals and the other solid metalloids.

Hence it follows that beyond a certain temperature, carbon, silicon, and boron also follow Dulong and Petit's law, and continue to do so as long as the temperature rises. Dulong and Petit's law has thus become one without exceptions. The wording of this law ought, however, to be somewhat different to what it has been up till now; the following would, perhaps, be best:—

"The specific heats of the solid elements vary acording to temperature; but for each element there is a point T_0 in the scale of temperature beyond which, as the temperature T rises, the variability of the specific heat becomes insignificant. The product obtained by multiplication of the atomic weight with that value of the specific heat which belongs to the temperatures $T > T_0$, is a nearly constant value for all solid elements, and lies between 5·5 and 6·5."

S. W.

MAGNETO-ELECTRIC MACHINES *

III.

FROM this property of the Gramme machine it may be employed to measure by the method of opposing currents any electromotive force. For this purpose it is only necessary to ascertain the velocity of rotation of the ring when the equilibrium between the currents is established. This may be measured in one of two ways—by the velocimeter of Deschiens, or by a chromoscopic diapason. The mode of operating with the latter when applied to the Gramme machine is thus described in M. Breguet's work. On the axis of the ring is mounted a small plate whose plane surface is covered with lamp-black by holding it over a candle. A tuning-fork vibrating one hundred times in a second, and carrying at one end a little style, is held in the hand, or, still better, fixed on a special support. At the precise moment that the two electromotive forces are shown by the galvanometer to be equal, the style is brought into contact with the blackened surface of the plate, upon which it traces a sinuous line. A very short contact is sufficient to give the required result. On stopping the machine, it will be seen to what fraction of the circumference ten sinuosities of the line traced on the plate correspond, from which it may be inferred in how many hundredths of a second the entire revolution of the ring has been accomplished. It is stated that if the ring in the Gramme machine be turned at a perfectly steady rate, the current produced will be more rigorously constant even than that of a Daniell's battery in good working order.

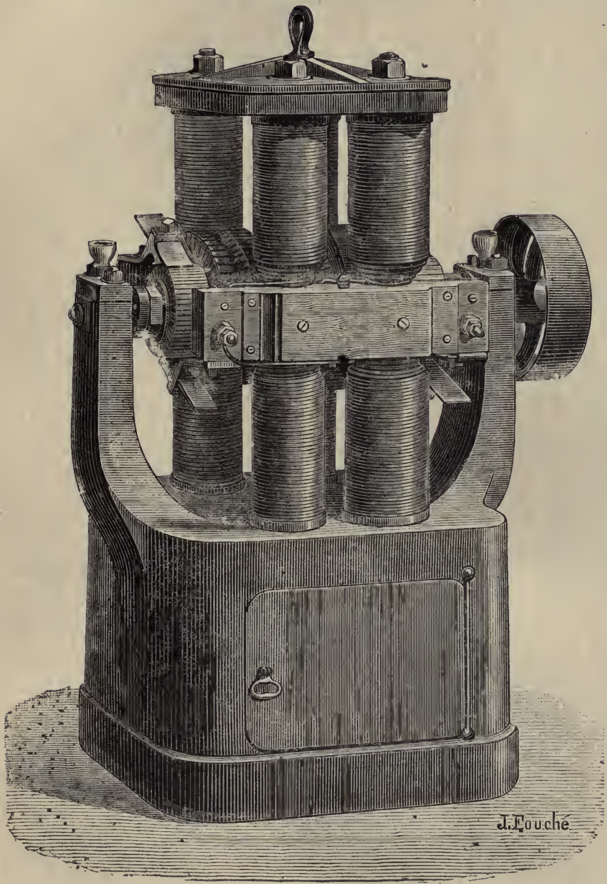

Fig. 7.—Gramme machine for metallic precipitations.

Fig. 7 represents a machine constructed with electro-magnets in 1872 by M. Gramme, which, with six others of the same kind, is in use in the well-known galvanoplastic establishment of Christofle and Co., of Paris. These machines weigh 750 kilogrammes, and the weight of copper used in their construction is about 175 kilogrammes. With a small engine of one-horse power, one of them will deposit 600 grammes of silver per hour. By some recent modifications in its construction this machine has been improved so as to increase the weight of silver deposited per hour to 2,100 grammes, or above 4½ lbs. In Figs. 8 and 9 we have the forms of the Gramme Machine now in use for the production of the electric light. They are improvements on the machine which was tried on the Clock Tower of Westminster Palace. This machine had the defect of becoming heated while at work, and of giving sparks between the metallic bundles of copper wire and the conductors from the helices. In the machine represented in Fig. 8 these defects are said to have been completely remedied. The entire machine weighs 700 kilogrammes, and there are 180 kilogrammes of copper in the electro-magnets, and forty kilogrammes in the two rings. It produces a normal light of 500 Carcel burners; but, by augmenting the velocity, it is asserted that the amount of light may be doubled. It does not become heated, nor does it produce any spark where the brushes are applied.

In Fig. 9 we have the latest improvements devised by M. Gramme for producing the electric light. In this machine there are only two bar electro-magnets and a single moveable ring placed between the electro-magnets. Its weight is 183 kilogrammes, and the entire weight of copper used in its construction, both for the ring and for the electro-magnets, amounts to forty-seven kilogrammes. Its normal power is about 200 Carcel burners, but this can be greatly augmented by increasing the velocity. It may be interesting to give the results of some experiments with this machine.

Number of turns.	Carcel burners.	Remarks.
650	77	No heating or sparks.
830	125	,, ,,
880	150	,, ,,
900	200	,, ,,
935	250	Slight heating, no sparks.
1025	200	Heating and sparks.

* The substance of a Lecture, with additions, delivered at the Belfast Philosophical Society, March 17, by Dr. Andrews, F.R.S., L. & E. (Continued from p. 132.)

By uniting two or more machines together, electrical currents of high tension may be obtained. But a more useful arrangement is to divide into two each ring, so that the two halves may be joined either for quantity or tension, and varied effects thus obtained from the same machine. This is effected in the following manner. Suppose the machine to contain sixty bobbins or helices round the ring. If the entrance of the thirty alternate bobbins is placed on one side of the ring and of the thirty other bobbins on the other side, there will be in reality two ring-armatures in one, interlaced as it were into each other; and by collecting the currents by means of two systems of rubbers, one to the right and the other to the left of the ring, we may obtain from each one half of the electricity produced by the rotation of the ring. By applying this principle to machines for producing the electric light, the same machine may give two distinct lights instead of one. In its industrial applications, this is a point of capital importance. The use of the electric light is at present greatly interfered with by its excessive brightness, and the deep shadows which by contrast are produced at the same time. These defects will be to a large extent remedied by the use of two lights, so that the shadow from one may be illuminated by the other. It is proposed to use four electric lights, each of the strength of fifty Carcel burners, for lighting foundries and large workshops. In support of this proposal I may remark that I find Duboscq's lamp of the latest construction gives a singularly steady and mild light, with only twenty Bunsen's cells, and would of course work equally well with currents of the same intensity from a magneto-electric machine.

It would be impossible, within the limits of this lecture, to give an account of the proposed improvements in magneto-electric machines, which will be found in the records of the Patent Office during the last three years. I cannot, however, pass over without notice the machine of Siemens and Alteneck, in which electrical currents are obtained solely by the rotation of a longitudinal helix of insulated wire. This helix revolves in an annular space bounded externally by two semi-cylindrical magnetic poles, and internally by a stationary cylinder of iron, which latter may also be an independent magnet. The following account of this apparatus I give nearly in the words of the inventors. Between the poles of one or more magnets or electro-magnets, an iron core or cylinder is placed so as to leave a space between it and the faces of the magnetic poles, which have a cylindrical form, and are concentric with the iron cylinder. In this annular space a cylindrical shell of light metal is made to revolve, on which a coil of insulated wire is wound parallel to the axis of the shell, and crossing its ends from one side to the other. There may be several such coils each covering an arc of the periphery of the shell. The ends of these wires are

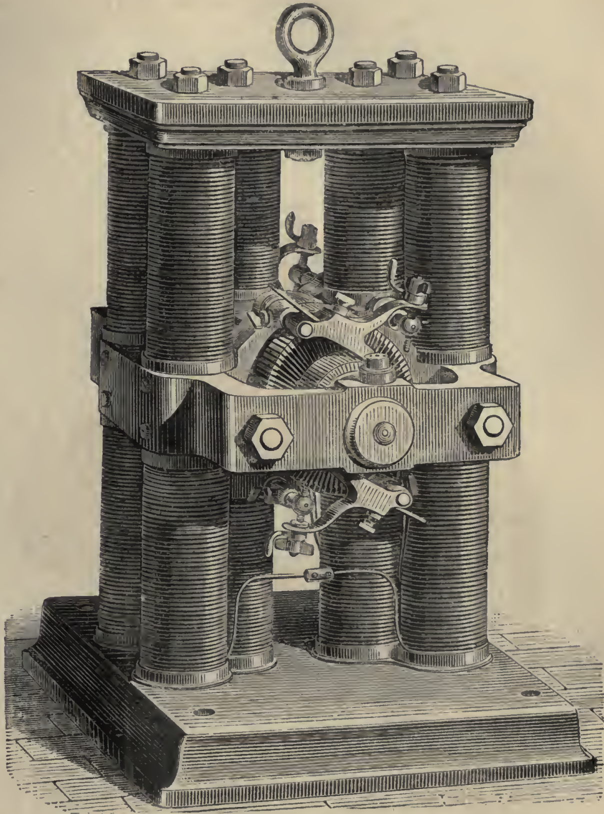

FIG. 8.—Gramme machine for electric light.

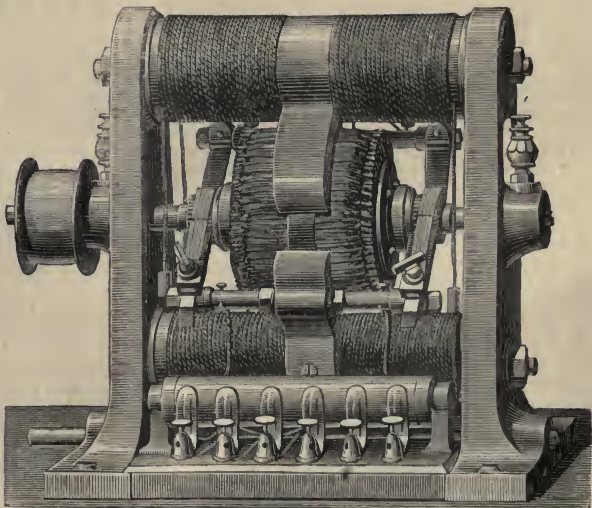

FIG. 9.—Gramme machine for electric light (latest form).

connected by metallic rollers or brushes with two stationary conductors, which are insulated, and constitute the poles of the machine. The currents obtained on rotating the shell may be made either continuous or intermittent, or they may be alternately reversed. The iron cylinder itself may be rendered magnetic by coiling upon it longitudinally an insulated wire after the manner of the rotating armature of Siemens.

To enumerate the possible applications of induction machines would be simply to describe all the applications which have already been made, or may hereafter be made, of current electricity to useful purposes. Among the former, the electric telegraph, the electric light, and electro-plating are perhaps the most important; among the latter, it will be sufficient to mention two proposals, one to facilitate the ascent of steep gradients by increasing, by means of magnetism, the adhesion of the wheels of locomotives to the iron rails; the other, to decompose, by electrolysis, common salt so as to obtain directly, and in a state of purity, the valuable chemical products hydrochloric acid and soda.

THE GOVERNMENT ECLIPSE EXPEDITION TO SIAM

THE following few details concerning the above Expedition will probably be of interest to the readers of NATURE; having just returned from Siam, I am unable at present to give full particulars. The general results obtained by our party have already been published in this country by means of the telegraph. The fact that any results were obtained at all is far more than might have been expected considering the very brief time we had to adjust the instruments. We had only five days to land, unpack, fit up, and test the instruments, most of which were quite new and untried. This want of time was in the first place owing to unavoidable delays on the way out, and to the fact that there was no steamer ready to take us on to the Observatory Camp at once, thus necessitating a visit to Bangkok prior to the eclipse. Our partial success is in a large measure due to the valuable assistance of Capt. A. J. Loftus, an English gentleman in the service of his Majesty the King of Siam; Capt. Loftus was sent out by his Majesty to prepare the camp for us at Choulai Point.

As previous to our departure from London there appeared in one of the leading journals a letter, signed "Monitor," in which some very unpleasant statements were made with regard to the probable reception our party would receive in Siam—although Mr. D. K. Mason, the Siamese Consul in London, published at the time a total denial of the absurd insinuations—I feel it my duty, in the name of all who took part in the expedition, to state that during our prolonged stay in the kingdom of Siam we received nothing but the greatest hospitality and kindness. Everybody, from the King downwards, showed the greatest desire to make our visit as pleasant as possible, and to aid the expedition in every way; difficulties were surmounted at great expense and trouble, and everything we asked for was at hand or was obtained with the least possible delay. Our drinking-water was brought nearly 100 miles by water to the camp; many tons of ice were brought up from Singapore, and every kind of wine was ready at hand.

The King sent several of his officials, both European and Siamese, to assist us, and ordered such observations to be made at Bangkok as the chief of the expedition, Dr. Schuster, might consider of use to the expedition; the King himself observed and made a drawing of the corona. Our camp and observatory were situated some fifty miles from the city of Bangkok, on the west of the Gulf of Siam, in the central line of totality. On our arrival we found what had formerly been a waste of jungle converted into a magnificent camp, and all the houses fitted up ready for our reception.

The eclipse itself differed from former ones in respect to the greater brightness of the corona and the smallness and fewness of the red flames. As far as we could make out, the time as calculated by the *Nautical Almanack* was some ten seconds wrong.

In a "Reuter's" telegram, Dr. Schuster stated that the spectroscopic cameras had failed. As failures arise from many sources, this must be regarded as only a general statement. It merely implied that no results were obtained by these instruments, not that as instruments for observing eclipses they were found to be a failure. Several of the instruments were to have been tested during the outward voyage, but owing to the breaking-down of the *Surat*, and consequent transshipment of cases, no opportunity for such work was found, and, on arriving at the camp, the time was far too short, owing to other accidents, to enable anything like satisfactory focussing and adjustments.

There were two sets of instruments employed as telespectropes, one working in the large observatory, the other in the Siderostat Observatory, where we had the large new siderostat working with Mr. Lockyer's 9¼-inch reflecting telescope and a spectroscopic camera. The first two instruments were in splendid order, working together beautifully, but the spectroscopic camera, not having been tested previously, could not be brought to give anything like a well-focussed photograph prior to the eclipse. The image of the corona, which appeared very distinct and bright on the slit-plate, although exposed during the whole of totality, gave no visible results on the photographic plate; even the sun itself, exposed for two seconds for the purpose of obtaining an index, gave likewise no result.

Before making any statements on the results obtained, I must wait the issue of the report of the Royal Society's Eclipse Committee.

Numerous drawings were sent in by the Siamese, which will be very valuable along with the general observations. After the eclipse, owing to three of our party being too ill to leave, we remained longer in the city of Bangkok than we had expected. During our stay Mr. and Mrs. Henry Alabaster, our hosts, on behalf of the King, entertained us in the most hospitable manner, taking care that those who were ill should have all possible attention, and be restored to health as fast as good doctors and kind nursing could accomplish it.

The following is a complete list of all who assisted us in the observatories during the eclipse, as well as of the members of the expedition sent out, with the part taken by each person:—

THE EXPEDITION.

Dr. ARTHUR SCHUSTER.—Chief of the Expedition; in charge of large Observatory, attending to the Equatorial.

FRANK EDWARD LOTT.—Dr. Schuster's Assistant. In charge of the Siderostat Observatory.

F. BEAZLEY, Jun.—Photographic Department. Developing negatives in dark room No. 1.

OSCAR ESCHKE.—Photographic Department. Preparing plates in dark room No. 2.

Officers from H.M.S. Lapwing.

Hon. H. N. SHORE, Lieut. R.N.—Taking drawings of Corona in large Observatory.

ANDREW LESLIE MURRAY, Nav. Lieut. R.N.—Keeping time in large Observatory by Chronometer from H.M.S. *Lapwing*.

W. J. FIRKS, Assist. Eng., R.N.—Attending to the clock of Mr. Penrose's instrument.

Europeans and Siamese from Bangkok.

Capt. A. J. LOFTUS, R.S.N.—Founder of the Observatory and Camp. In charge of Mr. Beazley's Camera, taking direct photographs of Corona with 2—4—8—16 seconds' exposure.

Mrs. M. Loftus.—Keeping time for Capt. Loftus.
Francis Chit.—Royal Photographer to the King. Preparing and developing in dark room No. 3 for Capt. Loftus.
W. Bray.—Attending to plates for Capt. Loftus.
F. G. Patterson.—Keeping time in large Observatory with Mr. Murray.
— Hendricke and W. H. Lang.—Attending to the Prismatic Camera in large Observatory.
C. Bethje.—Dr. Schuster's amanuensis during totality.
Capt. J. Thompson, R.S.N., and Edward H. Loftus.—Signalling time between the large Observatory and the Siderostat Observatory.
Capt. Chung, R.S.W.—In charge of thirty Siamese, guarding the Observatory ground.

Six Seamen from H.M.S. Lapwing.

Carpenter, Blacksmith, and Two Seamen in large Observatory, taking plates between dark rooms and instruments.
Two Seamen in Siderostat Observatory: one to bring plate from dark room and watch the Corona, and the other to open and shut the Camera slide.

It was not till the day of the eclipse that we got the instruments in anything like position, and even then they were but half tested. We then had a couple of rehearsals, and by mid-day everyone was fully prepared and thoroughly knew the part he would have to perform during totality. This was entirely due to the indefatigable and untiring manner in which Dr. Schuster examined into every detail, and to the readiness with which everyone, without exception, undertook the part allotted him, and did his utmost to understand all the requirements of the position.

After leaving Siam our party separated at Singapore, Dr. Schuster bound for Simla, Mr. Beazley for Japan and China, Mr. Eschke for Berlin, the writer alone returning to England with the results obtained by the Expedition.

Frank Edw. Lott

NOTES

The deaths of two eminent astronomers are announced: Prof. d'Arrest, of the University of Copenhagen, who died on June 14, in his fifty-third year; and Prof. Winlock, the distinguished Director of Cambridge Observatory, U.S.

We learn with the greatest pleasure that a thorough and systematic observation of the cirrus clouds is in the course of being established in other countries than Sweden. The great importance of these observations we recently urged on the attention of meteorologists in reviewing Dr. Hildebrandsson's "Essay on the Upper Currents of the Atmosphere," vol. xii. p. 123. Dr. Hildebrandsson has undertaken the discussion of these observations, and already the meteorological institutes and societies of Norway, Denmark, France, Austria, Portugal, and Scotland have promised their assistance and agreed to send to Sweden observations from several stations in their respective countries.

The following Commission has been appointed to inquire into "the practice of subjecting live animals to experiment for scientific purposes, and to consider and report what measures, if any, it may be desirable to take in respect of any such practice:"—Viscount Cardwell, Baron Winmarleigh, W. E. Forster, Sir J. B. Karslake, Prof. Huxley, Prof. Erichsen, and R. H. Hutton.

Dr. Gerald F. Yeo has been elected to the professorship of Physiology in King's College, London.

In vol. xi. p. 475, we announced the discovery of a boiling lake in the island of Dominica. The *Trinidad Chronicle* of May 21 contains an account of a visit to the spring by Mr. H. Prestoe, superintendent of the Trinidad Botanic Gardens. The lake lies in the mountains behind Roseau, and in the valleys around many *souffrières*, or solfataras, are to be met with. The Boiling Lake is a gigantic solfatara, with an excess of water-volume over the ejective power exerted by its gases and heat. It is affected by a very considerable volume of water derived from two converging ravines which meet just on its north-west corner, and owing to the existence of a small hill immediately opposite (which has had the effect of diverting the course of the ravine-water into its present channel), the action of the solfatara has caused the formation of a crater-like cavity, which is now the Boiling Lake with its precipitous and ever-wasting banks on its north and south sides, of some sixty feet depth. The temperature of the lake ranges from 180° to 190° F. The point of ebullition seems to vary its position somewhat; the water rising two, three, and sometimes four feet above the general surface, the cone dividing occasionally into three, as though ejected from so many orifices. During ebullition a violent agitation is communicated over the whole surface of the lake. The sulphurous vapour arises in pretty equal density over the whole lake, there being no sudden ejection of gas observed from the point of ebullition; there are no detonations; the colour of the water is a deep dull grey, and it is highly charged with sulphur and decomposed rock. As the outlet of the water is constantly deepening, the surface of the lake must gradually become lower, and it will, Mr. Prestoe thinks, ultimately be destroyed, and its character be changed to that of a geyser. It will then gradually fill up by the reduction of the adjacent hill-sides, and innumerable solfataras will be formed in the place of the present gigantic one. Mr. Prestoe found no bottom with a line of 195 feet, ten feet from the water's edge. One great result of the action of solfataras is the decomposition of the volcanic rock and the development therefrom of various kinds of gypsum. Some blocks met with have a very strong resemblance to the Tuscany or Volterra marble. Mr. Prestoe thinks that these large solfataras have had much to do in bringing about the present conformation of the district.

Dominica, which was formerly one of the chief coffee-producing countries, has of late years almost entirely ceased to grow the plant. The capabilities of the island, however, are apparently so great, not only for the cultivation of coffee, but also for many other food products, that the attention of the authorities has been directed to the matter, and the result is that Mr. Prestoe, of the Botanic Gardens, Trinidad, has been commissioned to examine and report on the prospects of the island generally, and the best means of developing its resources. We anxiously await the details of Mr. Prestoe's report upon an island so fertile and beautiful as Dominica, but which has, no doubt, through want of European capital and energy, been allowed to drift almost into an unprofitable waste.

The *Times* of last Thursday contains a letter, dated Yokohama, April 11, from its correspondent on board the *Challenger*, giving an account of the cruise from Mindanao by New Guinea and the Admiralty Islands to Japan. An extremely interesting account is given of the natives of New Guinea at Humboldt Bay and of the Admiralty Islanders. The following are the principal results of the soundings made:—The greatest depth in the section, 2,250 miles long, from the Admiralty Islands to Japan, was found on the 23rd of March in 4,575 fathoms, between the Carolines and Ladrones. This is the deepest trustworthy sounding on record, with the exception of two taken by the *Tuscarora* off the east coast of Japan, in 4,643 and 4,655 fathoms respectively, but no sample of the bottom was procured on either of these occasions. A second sounding gave 4,475 fathoms. The tube of the sounding machine contained an excellent sample of the bottom, which was of a very peculiar character, consisting almost entirely of the siliceous shells of *Radiolaria*. Three out of four Miller-Casella thermometers sent down to these depths were crushed to pieces by the enormous pressure they had to bear; the fourth withstood the pressure, and registered, when corrected for the pressure, at 1,500 fathoms, the usual temperature for that

depth, 34°·5 F.; so that at that place there is a layer of water at that uniform temperature occupying the bottom of the ocean trough of the enormous thickness of 3,075 fathoms (18,450 feet). The observations made in this section, taken in connection with others made elsewhere, would seem to point to the following law:—That "Globigerina ooze"—a rapidly forming deposit, containing the whole of the abundant carbonate of lime of the shells of the Foraminifera living on the surface and beneath it, and consequently consisting of almost pure carbonate of lime—generally occupies depths under 2,000 fathoms in the ocean; that beyond this depth, the proportion of the calcareous matter is gradually diminished, and the deposit, which now contains a considerable amount of clay, goes under the name of grey ooze; that at 2,600 fathoms the calcareous matter has almost entirely disappeared, and we have the purest form of "red clay," a silicate of alumina and iron with siliceous tests of animals; that from this point the "clay" decreases in proportion, and the siliceous shells increase, until at extreme depths the "clay" is represented by little more than a red cement, binding the shells together. As to the transition from the "Globigerina ooze" to the "red clay," the *Times* correspondent says, it is due to the removal of the lime of the Globigerina shells by water and carbonic acid, or in some other way; the apparent disappearance of the "red clay" is a fallacy produced by the increased proportion of the siliceous shells. It has now been ascertained by the use of the tow-net at great depths that Radiolarians and Diatoms inhabit the water all the way down, and are probably more abundant at greater depths; and it follows from this that four times more, at least, must die and shed their tests in 4,000 fathoms than in 1,000 fathoms. The most marked temperature phenomenon observed in the two sections was the presence of a surface layer of water of an average depth of 80 fathoms, and a temperature above 77° F., extending northwards from the coast of New Guinea about 20°, and westward as far as the meridian of the Pellew Islands. The greater part of this huge mass of warm water is moving with more or less rapidity to the westward.

M. JANSSEN was present at Monday's sitting of the Paris Academy.

THE preparations for the Geographical Congress in Paris are being actively completed. The large map of France executed by the staff officers will be exhibited, all the sheets having been joined, thus forming one continuous sheet of paper of immense size. The map will be exhibited at the Tuileries in the Salle des États. It will be photographed by the microscopical and panoramic process. There is a law prohibiting valuable documents in the National Library, Paris, from being taken out of the building. But a large hall will be set apart for their exhibition, and all the members of the Geographical Congress will get free admission to view them as often as they may desire.

M. LEVERRIER, at Monday's sitting of the Paris Academy, intimated that the great reflecting telescope, and other large apparatus, will be ready for inspection by the members of the Geographical Congress on their visit on the 5th of August.

MR. A. J. ANDERSON, from Manchester Grammar School, and Mr. T. W. Stubbs, from Clifton College, have been elected to Demyships in Natural Science in Magdalen College, Oxford. Mr. H. A. Wilson, of Magdalen College School, was at the same time elected to the Exhibition in Natural Science. The stipend of the Demyships is 95*l.* per annum, and of the Exhibition 75*l.* They are tenable for five years.

S. NALL has been elected to a Foundation Scholarship for proficiency in Natural Science at St. John's College, Cambridge. Stewart, Lowe, and Houghton to Exhibitions.

J. T. MÖLLER, of Wedel (Holstein), having been repeatedly requested to publish his process of preparing Diatomaceæ, has resolved to adopt the following plan:—If a sufficient number of subscribers is obtained, he will publish a work with illustrations, under the title of "The Preparation of the Diatomaceæ," which will contain—1. The collecting; 2. The cleaning and purifying (*a*) of the living subjects; (*b*) of dead subjects in the mud; (*c*) of fossils. 3. The separation of the different species. 4. The preparation and mounting (*a*) in the ordinary manner—in quantity; (*b*) as selected and arranged; (*c*) as "Typen- and Probe-platte," &c.

WE believe that the *Pandora*, which has just sailed to attempt the north-west passage, has been fitted out at the joint expense of Lady Franklin, Mr. James Gordon Bennett, Lieut. Lillingston, and Capt. Allen Young—the last-mentioned, however, bearing the major portion of the cost, as well as the whole risk of the voyage. We are glad to hear that the health of Lady Franklin, who has been seriously ill, has considerably improved. On Monday evening the *Pandora* finally left Plymouth for Disco. On the same day, the *Times* says, there was to sail from Sunderland Dock a small sloop named the *Whim*, bound to the Arctic seas and zone; it is under the command of Capt. Wiggins, of the merchant service, and is manned by five able seamen. The little vessel is only twenty-seven tons register. Capt. Wiggins is bound for the Russian coast.

ON Monday evening an extraordinary meeting of the Royal Geographical Society was held, at which the Seyyid of Zanzibar who was present, was received with great enthusiasm, and expressed his anxiety to do all in his power to forward the objects of the Society. Mr. John Forrest gave an account of his journey across the western half of Australia, from Champion Bay on the west coast to the Overland Telegraph line. We have already given some details of the journey in vol. xi. p. 93. Mr. Forrest concluded by stating that all the geographical problems have now been finally solved, and the only remaining portion of interest is the small part in the north-west corner from Roebuck Bay to the Victoria River.

AT the above meeting Dr. W. B. Carpenter read a paper on recent observations on ocean temperature made in the *Challenger* and *Tuscarora*, with their bearing on the doctrine of a general oceanic circulation, sustained by difference of temperature.

UNDER the heading of "Early Indications of Spectroscopy in America," the *American Chemist* for May reprints two papers by Dr. David Alter, from the *American Journal of Science* of 1854 and 1855, in which he describes some experiments made by him on the spectra of metals and gases, at least three years before the publication of the researches of Bunsen and Kirchhoff.

THE Sub-Wealden Exploration has made considerable progress during the past week. A further depth of 108 feet has been reached in five days, making a total of 1,246 feet.

THE most interesting objects which attract attention at the Southport Aquarium just now are the eggs of the Rough Hound (*Squalus catulus*), which were deposited in the tanks about the beginning of December of last year. All the eggs seem to be in a healthy condition, and the young fish are now so far advanced that their movements within their horny cases can be distinctly traced, and possibly only a short interval will elapse before they are completely free. Mr. Long anticipates a similar result from the eggs of the Skate (*Raia batis*) deposited in February last. The fine Sturgeon about eight feet long, and about thirty specimens of the Sea-horse (*Hippocampus brevirostris*) are also objects of much interest.

WITH reference to our note (vol. xii. p. 135) on the attempt to acclimatise humming-birds in Paris, a correspondent informs us

that Mr. Gould some years ago succeeded in bringing a living pair within the confines of the British Islands, and a single individual to London, where it lived two days. The birds were quite lively during the voyage across the Atlantic, but began to droop when off the coast of Ireland; and, as we have said, Mr. Gould succeeded in bringing only one to London alive. Particulars will be found in Mr. Gould's "Monograph of the Trochilidæ."

FURTHER details are to hand of the earthquake which on May 18 caused so much destruction in the valley of Cucuta, in the Republic of New Granada. The destruction to life and property has been almost unprecedented. The German drug store, it is stated, was set on fire by a ball of fire that was thrown out of the volcano, which, at the time the news left, was constantly belching out lava. The volcano has opened itself in front of Santiago, in a ridge called El Alto de la Giracho. In reference to this, see the letter we publish to-day from Mr. W. G. Palgrave.

THE final arrangements have been made for holding the forty-third annual meeting of the British Medical Association, which meets in Edinburgh this year on August 3, under the presidency of Prof. Sir Robert Christison, Bart.

AN exhibition is to be held in Belgium next year of all such apparatus, sanitary arrangements, or scientific appliances as are calculated to preserve health or to save life.

WITH the *Gardener's Chronicle* of last Saturday is published a beautifully illustrated supplement, giving an account of Chatsworth, the seat of the Duke of Devonshire.

THE Brussels Académie Royale has just published a new edition of its "Notices Biographiques et Bibliographique." This volume contains a brief sketch of the history of the Academy, a list of Presidents, honorary, corresponding, and ordinary members and associates in the various classes, followed by brief biographical notices of all the members who have contributed papers, with full lists of their contributions. The volume is a very valuable as well as a very interesting one.

MESSRS. TRÜBNER AND CO. have published a pamphlet by Dr. A. Stœcker (translated by Dr. Harrer) giving much useful information concerning the baths and mineral springs of Wildungen, about one hour's distance from Cassel. The springs, of which there are five in use, are more or less alkaline-chalybeate, and seems to possess important curative qualities. In connection with this subject the following recently published statistics of the numbers of patients that visited the German and Hungarian watering-places during 1874 will be interesting:—Baden-Baden, 41,464; Buziasch, 813; Carlsbad, 20,235; Elster, 4,373; Franzensbad, 7,655; Gleichenberg, 3,373; Gastein, 1,253; Gmunden, 1,202; Giesshübl, 12,625; Gräfenberg, 847; Hall, 2,000; Ischl, 9,386; Ilmenau, 1,468; Krankenheil, 1,010; Königswart, 313; Neuenahr, 3,405; Oeynhausen, 3,254; Kryniza, 2,080; Luhatschowitz, 942; Marienbad, 9,861; Nanheim, 4,152; Pystian, 1,709; Reichenhall, 4,215; Reinerz, 2,352; Rohitsch, 2,603; Szczawinca, 2,033; Teplitz-Trentschin 1,655; Tüffer, 2,061; Vöslau, 3,865; Wartenberg, 805; Warmbrunn, 1,960; and Wiesbaden, 65,800.

THE additions to the Zoological Society's Gardens during the past week include a Black-backed Jackal (*Canis mesomeles*) from S. Africa, presented by Messrs. Donald Currie and Co.; an Indian Coucal (*Centropus rufipennis*) from India, presented by Mrs. Hunter Blair; a Small Hill Mynah (*Gracula religiosa*) from S. India, presented by Sir Charles Smith, Bart.; a Golden Eagle (*Aquila chrysäetos*) from India, presented by Mrs. Logan Horne; two Chinese Quails (*Coturnix chinensis*) from China, presented by Mr. A. Jamrach; two Virginian Eagle Owls (*Bubo virginianus*) from N. America, deposited; two White-winged Choughs (*Corcorax leucopterus*) from Australia, a Salle's Amazon (*Chrysotis sallœi*) from St. Domingo, purchased; five Australian Wild Ducks (*Anas superciliosa*) bred in the Gardens.

RECENT PROGRESS IN OUR KNOWLEDGE OF THE CILIATE INFUSORIA *

III.

IT follows from this view that the cavity of the Cœlenterata would represent an intestinal cavity only, while a true body cavity would be here entirely absent. This way of regarding the cavity of the Cœlenterata is at variance with the conclusions of most other anatomists who regard the cœlenterate cavity as representing a true body cavity, or a body and intestinal cavity combined. I had myself long entertained the generally accepted opinion that the cavity of the Cœlenterata represents a body cavity. I must, however, now give my adhesion to the doctrine here advocated by Haeckel, and regard the proper body cavity of the higher animals as having no representative in the Cœlenterata. I believe that this is supported both by the facts of development and by the structure of the mature animal. Indeed, the body cavity first shows itself, as Haeckel has pointed out, in the higher worms, and is thence carried into the higher groups of the animal kingdom.

If such be the real nature of a true intestinal cavity and of a true body cavity, it is plain that neither the one nor the other can exist in the Infusoria, for there is here nothing which can be compared with either the endoderm or the ectoderm.

The whole, then, of the alleged chyme of the Infusoria is nothing more than the internal soft protoplasm of the body. It is quite the same as in Amœba and many other unicellular animals.

The peculiar currents which have been long noticed in the endoplasm of many Infusoria must be placed in the same category with the rotation of the protoplasm observed in many organic cells. Von Siebold, indeed, had already compared the endoplasm currents of the Infusoria to the well-known rotation of the protoplasm in the cells of Chara.

The presence of a mouth and anal orifice in the ciliate Infusoria has been urged as an argument against the unicellular nature of these organisms. The so-called mouth and anus, however, admit of a comparison not in a *morphological* but only in a *physiological* sense with the mouth and anus of higher animals. They are simple lacunæ in the firm exoplasm, and have, according to Haeckel, no higher morphological value than the "pore canals" in the wall of many animal and plant-cells, or the micropyle in that of many egg-cells. Kölliker had already compared them to the excretory canal of unicellular glands. Since, therefore, they do not admit of being homologically identified with the orifices of the same name in the higher animals, Haeckel proposes for them the terms "*Cytostoma*" and "*Cytopyge*."

So also the presence of a contractile vesicle and of other vacuoles affords no solid argument against the unicellularity of the Infusoria. The physiological significance of the contractile vesicles has been variously interpreted. In certain cases a communication with the exterior appears to have been demonstrated, and Haeckel regards them as combining two different functions of nutrition, namely, respiration and excretion. They are in all cases destitute of proper walls, and they have been long recognised as morphologically nothing more than lacunæ filled with fluid. Regular contractile vesicles differing in no respect from those of the ciliate Infusoria are often found in the Flagellata and in the swarmspores of many Algæ.

Besides the constant and regular contracting vacuoles, there occur also others less constant and less regularly contracting. These are found in the softer endoplasm, while the constant and regularly contracting vacuoles occur for the most part in the firmer exoplasm. One is just as much a wall-less vacuole as the other, and the difference between them is to be traced to the difference of consistence in the surrounding protoplasm. Haeckel regards the less constant ones as the original form from which the others have been phylogenetically derived, that is, by a process of inheritance and modification through descent.

The last and most important of the parts which enter into the formation of the Infusorium body, namely, the nucleus, is next discussed. Viewed from a morphological point, it has been already demonstrated that the nucleus is in all Ciliata originally a single simple structure, resembling in this respect a true cell-nucleus. As the Infusorium body approaches maturity we find that with its advancing differentiation peculiar changes occur in the nucleus just as in the rest of the protoplasm, but these changes are entirely paralleled by differentiation phenomena

* Anniversary Address to the Linnean Society, by the President, Dr. G. J. Allman, F.R.S., May 24. Continued from p. 157.

which are known in other undoubted cell-nuclei, as, for example, in the germinal vesicle of many animals, in the nuclei of many unicellular plants, the nuclei of many parenchyma cells of the higher plants, and the nuclei of many nerve-cells. The mature Infusorium nucleus is often vesicle-like, and consists of a delicate investing membrane and fine granular contents, precisely as in the differentiated nucleus of many other cells. In many Ciliata, if not in all, there is within the young nucleus a dark, more refringent corpuscle, which has quite the same relations as the nucleolus of a true cell-nucleus.

Regarded from a physiological, no less than from a morphological point of view, the Infusorium nucleus and true cell nucleus admit of a close comparison with one another. It may be considered as established by the concurrent observations of all investigators, that the nucleus of the Infusoria performs the function of a reproductive organ, though the opinions entertained as to the mode in which it thus acts are extremely divergent.

It is now admitted that in the reproduction of unicellular organisms both in the animal and vegetable kingdom, the nucleus takes an important part, and by its division as a primary act ushers in the division of the rest of the protoplasm. Even in the cells which form constituents of tissues, the part played by the nucleus is altogether similar, its division always preceding the division of the cell itself.

In quite a similar way does the nucleus behave in the ciliate Infusoria. The non-sexual reproduction of the Infusoria by division is perhaps universal. In such cases the division always begins by the spontaneous halving of the nucleus, and this is followed by a similar division of the surrounding protoplasm, exactly as in the ordinary simple cell.

Another phenomenon in which the nucleus plays an important part is named by Haeckel "spore formation." Under this designation he comprehends all those cases in which—the idea of a previous fecundation being rejected—the nucleus breaks into numerous pieces, and each of these, apparently by becoming encysted in a portion of the protoplasm of the mother body, shapes itself into an independent cell—a so-called germ-globule, (*Keimkugel*). Now this is a true spore—just as much so as the spores which arise quite in the same way in unicellular plants. The whole process is to be regarded as a case of the so-called endogenous multiplication of cells.

Most authors, however, take a different view of the nucleus. Following Balbiani, they regard it as an ovary; and to the fragments into which it breaks up they assign the significance of eggs; while the so-called nucleolus, which lies outside the nucleus, is, as we have seen, believed to be a testis in which spermatozoa are developed for the fecundation of the eggs.

We must bear in mind, however, that this "nucleolus" has been hitherto found in but a disproportionately small number of species, while the spermatozoal nature of the apparent filaments which have been noticed in it has by no means been proved; and we have already seen that some observed facts such as those adduced by Bütschli are opposed to the view which would assign to them the nature of true spermatozoa.

As Haeckel remarks, however, even though the so-called nucleolus be really a testis fecundating the eggs or fragments derived from the breaking up of the nucleus, this would afford no valid argument against the unicellularity of the Infusoria, for precisely the same sexual differentiation and reproduction are found in unicellular plants.

It may now, then, be regarded as proved that the process by which the body of the ciliate Infusorium attains a certain degree of differentiation is repeated not only in other unicellular organisms, but in many parenchyma cells both of plants and animals. The difference, as Haeckel with much force points out, between the differentiation process of these parenchyma cells and that of the Infusorium body consists in the fact that in the parenchyma cells the differentiation is a one-sided one, conditioned by the division of labour in the organism of which they form the constituents, while in the Infusorium it is a many-sided one related to all the different directions in which cell-life manifests itself, and resting on a physiological division of labour among the "plastidules" or protoplasm molecules. In other words, the differentiation processes which in multicellular organisms are found distributed among different cells, are united in the single cell of the ciliate Infusorium, thus leading to the formation of an animal very perfect in a physiological point of view, but which morphologically does not pass the limit of a simple cell.

In some rarer cases the Infusorium body is found to enclose two or more nuclei, and Haeckel admits that such Infusoria must strictly be regarded as multicellular, since the nucleus in itself alone determines the individuality of the cell; but these exceptional cases have no significance for the main conception of the infusorial organism. The multiplication of the nucleus exerts almost no influence on the rest of the organisation, and such "multicellular ciliata" are to be compared with the colony-building forms of the Acinetæ, Gregarinæ, Flagellatæ, and other undoubtedly unicellular organisms.

In conclusion, Haeckel considers the systematic position of the Infusoria. That they are genuine *Protozoa*, having no direct relation to either the Cœlenterata or the Worms, must be now admitted. To this result we are led in the most convincing way by all that we know of their development. In all the animal types which stand above the Protozoa, the multicellular organism is developed out of the simple egg cell by the characteristic process of segmentation, and the cell masses so arising differentiate themselves into two layers—the endoderm and the ectoderm, or the two primary germ lamellæ.* Resting on the fundamental homology of these two layers in all the six higher types of the animal kingdom, Haeckel had already † directed attention to the fact that all these types pass in their development through one and the same remarkable form, to which he gives the name of Gastrula, and which he regards as the most important and significant embryonal form of the whole animal kingdom. This gastrula consists of a multicellular, usually oviform uniaxial, body enclosing a simple cavity—the primordial stomach or intestine cavity, which opens outward on one pole of the axis by a simple orifice—the primordial mouth, and whose walls are composed of two layers, the endoderm or inner germ lamella, and the ectoderm or outer germ lamella.

This larval form has now been shown by the researches of Haeckel, Kowalevsky, Ray Lankester, and others, to occur in members of all the six higher primary groups of the animal kingdom; and Haeckel, in conformity with what he has called the biogenetic fundamental law ‡—the recapitulation of ancestral forms in the course of the development of the individual—had already in a former work § concluded in favour of a common descent of all the six higher types from a single unknown ancestral form which must have been constructed essentially like the Gastrula, and to which he gives the name of *Gastræa*.

From this common descent the Protozoa alone are excluded, these not having yet attained to the formation of germ lamellæ or of a true intestinal cavity.

He regards this difference between the development of the Protozoa and that of all the other animal types as so important, that he founds thereon a fundamental division of the whole animal kingdom into two great primary sections—the *Protozoa* and the *Metazoa*. The former never undergo segmentation, never develop germ lamellæ, and never possess a true intestinal cavity; the latter, which include all the other types of the animal kingdom, present a true segmentation of the egg cell, have all two primary germ lamellæ—endoderm and ectoderm—a true intestine formed from the endoderm, and a true epidermis from the ectoderm; they all pass through the form of the gastrula, or an embryonic form capable of being immediately deduced from it, and (hypothetically) are all descended from a Gastræa.

The only Metazoa which in their existing condition have no intestine are the low worm-groups—Cœstoda and Acanthocephala—but these form only an *apparent* exception, for the loss of their intestinal canal is a secondary occurrence caused by parasitism, and Haeckel regards them as having descended from worms in which the intestine was present.

Several years ago Haeckel united into a separate kingdom, under the name of Protista, certain low organisms, some of which had been previously placed among the Protozoa, while others had been assigned to the vegetable kingdom. To this neutral group he refers the Monera, the Flagellatæ, the Catallactæ, the Labyrinthuleæ, the Micromycetæ, and the Acytariæ and Radiolariæ. After the elimination of these there remain as genuine Protozoa the Amœbinæ, the Gregarinæ, the Acinætæ, and, above all, the the true Infusoria or Ciliata.

The union of the Protista into a distinct kingdom equivalent in systematic value with the animal or vegetable kingdom, can, however, scarcely be maintained. We already know enough of some of them to justify our assigning these to one or other of the two generally accepted organic kingdoms; and there can be little doubt that, did we know the whole history of the others, as well as the essential difference between the animal and vege-

* The comparison of the endoderm and ectoderm of the Cœlenterata to the two primary germ lamellæ of the Vertebrata was first made by Huxley.
† "Die Kalkschwämme," 1872.
‡ "Generelle Morphologie."
§ "Die Kalkschwämme.

table kingdom, these, too, would be referred without hesitation either to the one or to the other, some passing to the former and others to the latter. The group of the Protista is thus at best but a provisional one, based partly on our ignorance of the structure and life-history of the beings which compose it, and partly on our inability to assign to the animal its essential difference from the plant. Haeckel, however, has done well in specially directing attention to it, and in his admirable researches on many of the organisms which he has thus grouped together he has largely contributed to our knowledge of living forms.

I have thus dwelt at considerable length upon this important paper of Haeckel's, because I think that it not only brings out in a clear light the essential features of infusorial structure and physiology as demonstrated by recent research, but that it goes far to set at rest the controversy regarding the unicellularity and multicellularity of the Infusoria.

Balbiani has quite recently published a very interesting account of the remarkable Infusorium long ago described by O. F. Müller under the name of *Vorticella nassuta*, and more recently taken by Stein as the type of his genus Didinium.

The animal, which is somewhat barrel-shaped, with an anterior and a posterior wreath of cilia, has one end continued into a proboscis-like projection which carries the oral orifice on its summit, while an anal orifice is situated on the point diametrically opposite to this. There is a very distinct cuticle, though the rest of the cortical layer is very thin, and can scarcely be optically distinguished from the internal parenchyma, which exhibits manifest currents of rotation. These flow in a continuous sheet along the walls from the anal towards the oral side, and on arriving at the mouth turn in towards the axis and then flow backwards along this until they complete the circuit by once more reaching the anal side of the body. No trichocysts are developed in the walls of the body. The contractile vesicle is large, and is situated near the anal end; it presents very distinct pulsations, and Balbiani is disposed to believe in a communication between it and the exterior.

During the act of digestion a tubular cavity can be seen running through the axis of the body, and connecting the oral and anal orifices. This is regarded by Balbiani as a permanent digestive canal. The post-oral or pharyngeal portion of this tube possesses a very remarkable feature, namely, a longitudinal striation caused by rigid rod-like filaments which are developed in its walls, and which can be easily detached and isolated by pressure or by the action of acetic acid. They then resemble some common forms of the raphides developed in the cells of plants. The function of these rods becomes apparent when the animal is observed in the act of capturing its prey. The Didinium is eminently voracious and carnivorous, and when in pursuit of other living Infusoria, such as Paramecium, the prey may be seen to become suddenly paralysed on its approach. A careful examination will then show that the Didinium has projected against it some of its pharyngeal rods, and to the action of these bodies the arrest of motion is attributed. A curious cylindrical tongue-like organ is now projected from the mouth towards the arrested prey, to which it becomes attached by its extremity. By the retraction of this tongue the prey is now gradually withdrawn towards the mouth, engulphed in the distended pharynx, and pushed deeper and deeper into the axial canal, where it is digested, and the effete matter ultimately expelled through the anus.

From all this Balbiani concludes against the unicellular doctrine. He sees in the axial cavity a permanent alimentary canal, and in the surrounding parenchyma a true perigastric space filled with a liquid which corresponds with the perigastric liquid of the polyzoa and of many other lower animals. He is not, however, disposed to make too broad a generalisation, and to insist on the presence of an alimentary canal distinct from a body cavity in all the other Infusoria. Here, however, he falls in with the views of Claparede and Lachmann and of Greeff, and maintains that as a rule the digestive and body cavity in the Infusoria are confounded into a single gastrovascular system.

Independently, however, of the untenableness of the conception of a united digestive and body cavity, it does not appear to me that Balbiani makes out any case against the unicellularity of the Infusoria. He admits that except in the pharyngeal and anal portion there is no evidence of a differentiated wall in his so-called digestive canal, and even though it be conceded that the middle portion of this canal constitutes a permanent cavity in the parenchyma, it would not differ essentially from other lacunæ permanently present in the protoplasm of many undoubtedly unicellular organisms. It has been already remarked that a communication between these lacunæ and the external medium is paralleled in many simple cells, and these external communications in Didinium present no feature essentially different.

The pharynx appears to be bounded by an inflection of the cortical layer, and I believe we may regard the rod-like corpuscles here present as a peculiar modification of the trichocysts which in many other Infusoria are developed in the cortical layer of the body. The projectile tongue-like organ is one of the most remarkable features of Didinium; we must know more, however, than Balbiani has told us of it, before we can decide on its real import. It is not improbably a pseudopodial extension of the protoplasm.

Balbiani has followed the Didinium through the process of transverse fission. This is preceded by the formation of two new wreaths of cilia, between which the constriction and division takes place, each half previously to actual separation developing within it such parts as it had lost in the act of division. The only part which in this act becomes divided between the two resulting animals is the nucleus. The so-called nucleolus was not seen by Balbiani, and though he observed two individuals in conjugation by their opposed oral surfaces, he never witnessed anything like the formation of eggs or embryos.

I believe I have now laid before you the principal additions which during the last few years have been made to our knowledge of the Infusoria. But though it will be seen that the labourers in the special field of microscopical research, to which I have confined this address, have been neither few nor deficient in activity, it must not be imagined that the subject has been exhausted, or that many questions, more especially such as relate to development, do not yet await the results of future investigations for their solution.

PRIZES OF THE FRENCH ACADEMY

As our readers are aware, the Paris Academy of Sciences holds at the end of December each year a solemn meeting for hearing *éloges* of the departed members, and delivering prizes to the most deserving essayists. But owing to the calamity of the war the prizes for 1873 were distributed in the end of 1874, and the prizes for 1874 remained undistributed. An extraordinary solemnity was celebrated on June 21, for the distribution of the 1874 prizes, and henceforth we hope nothing will prevent the Academy fulfilling its yearly duties with punctuality. M. Bertrand, the new perpetual secretary, read an essay on the life and works of M. Élie de Beaumont, his predecessor in the office. Since Abbé Duhamel, the first of these perpetual secretaries, died, this has been the constant practice. So Abbé Duhamel was praised by Fontenelle, Fontenelle by Fouchy, Fouchy by Condorcet, &c. &c. But M. Élie de Beaumont did not produce any *éloge* on Arago; it will be the next duty M. Bertrand will have to perform, and a very attractive one it is. The following are the results of last year's competition as announced at the meeting:—

1. Grand Prize in the Mathematical Sciences for a Mathematical Theory of the Flight of Birds was not awarded, though 2,000 francs were given to M. Penaud, the author of one of the memoirs, and an "encouragement" of 1,000 francs to the two authors of another memoir, MM. Hureau de Villeneuve and Crocé-Spinelli.

2. This was also the case with the Grand Prize in the Physical Sciences, the subject being Fecundation in Mushrooms. The value of the prize was, however, divided between the authors of two memoirs, viz., MM. Maxime Cornu and Ernest Rose, and M. Sicard.

3. The Poncelet Prize in Mechanics was awarded to M. Bresse, Engineer-in-chief des Ponts et Chaussées, for his work entitled "Cours de Mécanique Appliquée," and particularly for the great progress shown in the part devoted to the resistance of materials.

4. The Montyon Prize in Mechanics to M. Peaucellier, Lieutenant-Colonel of Engineers, for his researches on the transformation of alternate rectilineal motion into alternate circular motion.

5. The Plumey Prize to M. Joseph Farcot for his *servo-moteur*, or *moteur-asservi*, an apparatus which renders the action of the rudder more certain and more easy.

6. The Lalande Prize in Astronomy is a sextuple one, and was divided among MM. Mouchez, Bouquet de la Grye,

Fleuriais, André, Héraud, and Tisserand, as a reward for their observations of the Transit of Venus.

7. The Montyon Prize in Statistics was awarded to M. de Kertanguy, and honourable mention was made of MM. de St. Genis and Loua.

8. The Jecker Prize was divided into two, 3,000 francs being awarded to Prof. Reboul of Besançon for his work on the Ethers of Glycide and on the Hydrocarburets; and 2,000 francs to M. Bouchardat for his researches on the Ethers of Mannite and of Dulcite.

9. The Desmazières Prize was awarded to M. J. de Seynes for his study of many cryptogamic plants belonging to the genus *Fistulina*, and especially of *F. hepatica*.

10. The Fons Mélicocq Prize was divided by way of encouragement between M. Calley, author of a catalogue of vascular plants of the Department of Ardennes, and MM. Eloi de Vicq and Blondin de Brutelette, authors of a Catalogue Raisonné of vascular plants of the Somme.

11. The Thore Prize in Anatomy and Zoology, to M. Auguste Forel for his work "Les Fourmis de la Suisse."

12. The Bréant Prize of 100,000 francs always offered for the treatment of cholera was not awarded. A reward of 3,500 francs was accorded to M. Ch. Pellarin for his studies on the character and modes of transmission of cholera. For similar studies a reward of 1,500 francs was given to M. Armieux.

13. The Montyon Prize in Medicine and Surgery was divided as follows:—2,400 francs each to MM. Dieulafoy, Melassez, and Méhu: honourable mention and 1,000 francs to MM. Béranger-Féraud, Létiévant, and Péter.

14. Two Montyon Prizes of equal value, in Experimental Physiology, were awarded, one to MM. Arloing and Tripier for their experimental research on the conditions of persistence and sensibility in the peripherical end of divided nerves; and the other to M. Sabatier for his studies on the heart and the central circulation in the Vertebrata.

15. The proceeds of the Tremont Prize for 1873-4-5 were awarded to Prof. Achille Cazin.

16. The Gegner Prize was given to M. Gaugain to aid him in his researches in electricity and magnetism.

17. The Laplace Prize, consisting of a collection of the works of Laplace, was bestowed upon M. Badoureau, pupil of the first rank, 1874, in the École Polytechnique, and student in the Ecole des Mines.

Several prizes were not awarded.

The following are the subjects proposed for the next competition:—

1. Grand Prize in the Mathematical Sciences for 1876:—To deduce from a new and thorough examination of ancient observations of eclipses the value of the apparent secular acceleration of the mean movement of the moon; to fix the limits of exactness which the determination bears. Value of the prize, 3,000 francs.

2. Another Grand Prize of the same value in the Mathematical Prizes for 1876:—Theory of the singular solutions of equations for partial derivatives of the first order.

3. Grand Prize of 3,000 francs in the Mathematical Sciences for 1877:—Application of the theory of elliptic or Abelian transcendentals to the study of algebraic curves.

4. Grand Prize of 3,000 francs in the Physical Sciences for 1876:—To investigate the changes which take place in the internal organs of insects during complete metamorphosis.

5. Another Grand Prize of 3,000 francs in the Physical Sciences for 1876:—Investigation into the mode of distribution of marine animals on the coast of France.

6. Grand Prize of 3,000 francs in the Physical Sciences for 1877:—Comparative study of the internal organisation of various Edraiophthalmous Crustaceans which inhabit the European seas.

7. Extraordinary Prize of 6,000 francs on the application of steam to war-ships.

8. The Poncelet Prize (annual), intended to reward the work most useful to the progress of the mathematical sciences, pure or applied, which will have been published during the last ten years. Value 2,000 francs, with a copy of the complete works of Poncelet.

9. The Montyon Prize (annual) of 427 francs:—Agricultural or Industrial Mechanics.

10. The Plumey Prize (annual) of 2,500 francs:—Improvements in steam-engines.

11. The Dalmont Prize (triennial) of 3,000 francs, to be awarded in 1876, is confined to engineers "des ponts et chaussées."

12. The Bordin Prize of 3,000 francs:—To find a means of doing away with, or at least of seriously diminishing the inconvenience and the dangers which arise from the products of combustion issuing from the chimneys of railway-engines and of steamboats, as well as in towns from the proximity of furnaces.

13. The Lalande Prize (annual) of 542 francs is offered to the work most useful to Astronomy.

14. The Damoiseau Prize (the value not indicated):—To review the theory of the Satellites of Jupiter; to examine the observations and deduce from them constants, particularly that relative to the speed of light; finally, to construct special tables for each satellite.

15. Vaillant Prize (biennial) of 4,000 francs, to be awarded in 1877, to the best work on the planetoids.

16. The Valz Prize (annual) of about 500 francs, to be awarded in 1877 to the author of the best charts relating to the region of the invariable plane of the solar system.

17. The Bordin Prize of 3,000 francs:—To determine the temperature of the solar surface.

18. The Montyon Prize (annual) of 453 francs:—Statistics of France.

19. One or more Jecker Prizes (annual) for works on Organic Chemistry.

20. The Barbier Prize (annual) of 2,000 francs, for a medical, surgical, or pharmaceutical discovery.

21. The Alhumbert Prize of 2,500 francs, to be awarded in 1876:—The method of nutrition of mushrooms.

22. The Desmazières Prize (annual) of 1,600 francs, for the best work on cryptogamy, published in the year which precedes that of the competition.

23. The Fons Mélicocq Prize (triennial) of 900 francs, to be awarded in 1877 to the author of the best botanical work on the North of France.

24. The Thore Prize (annual) of 300 francs, intended to reward alternatively researches on the cellular cryptogams of Europe, or on the habits and anatomy of an insect.

25. The Bordin Prize of 1876, of 3,000 francs:—To study comparatively the structure of the teguments of the seed in angiospermous and gymnospermous plants.

26. Another Bordin Prize for 1877, of 3,000 francs:—To study comparatively the structure and the development of the organs of vegetation in the Lycopodiaceæ.

27. The Morogues Prize (quinquennial), value not indicated, to be awarded to the author of the best work on Agriculture.

28. The Savigny Prize of about 1,000 francs is intended to reward a young zoological traveller.

29. The Bréant Prize of 100,000 francs, offered to whoever discovers the means of preventing Asiatic cholera or the causes of that malady.

30. Montyon Prizes (annual) in Medicine and Surgery.

31. Serres Prize (triennial) of 7,500 francs, for the best work on general embryogeny applied as far as possible to physiology and medicine.

32. Godard Prize (annual) of 1,000 francs, for the best memoir on the anatomy, physiology, or pathology of the genito-urinary organs.

33. Montyon Prize (annual) of 764 francs, in experimental physiology.

34. One or more Montyon Prizes (annual) in the Industrial arts.

35. Trémont Prize (annual) of 1,100 francs, intended to encourage any *savant*, *artiste*, or mechanician who may be thought worthy.

36. The Geger Prize (annual) of 4,000 francs, "to support a poor *savant* who has signalised himself by important researches."

37. The Cuvier Prize (triennial) of 1,500 francs will be awarded in 1876 to the best work on the animal kingdom or on geology which will have appeared in the years 1873-75.

38. The Delalande-Guérineau Prize (biennial) of 1,000 francs, to be awarded in 1876 to the French traveller or *savant* who will have rendered the best services to France or to science.

39. The Laplace Prize (annual), consisting of a collection of the complete works of Laplace, to the pupil of first rank leaving the École Polytechnique.

The limit for the competitions for the above prizes is the 1st of June of the year in which the prize is to be awarded.

SOCIETIES AND ACADEMIES

London

Linnean Society, June 17.—Dr. G. J. Allman, F.R.S., president, in the chair.—Mr. J. E. Howard, F.R.S., made some observations on *Cinchona anglica*, a hybrid between *C. Calisaya* and *C. succirubra*.—Dr. Pryor exhibited specimens of *Myrsine Urvillei*, from New Zealand, which appeared to be hardy in this country.—The following papers were read:—1. On the affinities and febrifuge properties of the Aristolochiaceæ, by Mr. Clark.—2. On *Whitfieldia*, by Mr. S. Moore.—3. On the anatomy of *Amphioxus*, by Prof. E. R. Lankester, F.R.S. The author described the anatomy of *A. lanceolatus* as worked out in a series of sections made from numerous specimens collected by him at Naples. In opposition to Stieda, the truly perforate structure of the pharynx was asserted. A true body cavity or cœlom, distinct from the atrial chamber, was described, and it was shown to expand and attain a large development in the post-atrioporal region of the body. A pair of pigmented canals were described, apparently representing the vertebrate renal organ in a degenerate or else a rudimentary condition. Johannes Müller's pores of the lateral canals were shown to be hyoid slits leading into the pharynx. The attachment of the pharyngeal bars to the wall of the atrium by a series of pharyngo-pleural septa was minutely described. It was further shown that the marginal ridges of the ventral surface (metapleura) are hollow, containing a lymph-space, and that they, as well as the plates of the ventral integuments, disappear when the atrial chamber is largely distended with the sexual products. Drawings by Mr. W. J. Fanning, of Exeter College, were exhibited in illustration of the above statements.

Physical Society, June 26.—Prof. G. C. Foster, vice-president, in the chair.—Mr. W. J. Wilson read a paper on a method of measuring electrical resistance of liquids. Great difficulty has hitherto been experienced in measuring the resistance of electrolytes on account of the polarisation of the electrodes, and most of the methods hitherto employed have aimed at reducing this to a minimum by using large electrodes and very weak or rapidly alternating currents. The determinations, however, are difficult and require to be quickly performed. The following method is easy and is free from both the above objections. The arrangement in its most simple form consists of a long narrow trough filled with the liquid to be measured, say dilute acid. A porous pot containing a zinc plate in sulphate of zinc being placed in the acid at one end of the trough, and a similar pot with a copper plate in sulphate of copper in the acid at the other end, the whole arrangement forms a sort of elongated Daniell's cell, the chief resistance of which is in the long column of acid. The circuit between the plates being completed through a resistance box and mirror galvanometer, the current is shunted until a suitable deflection is obtained. One of the porous pots is now moved along the trough towards the other, and, as the resistance of the circuit is thus reduced by shortening the column of acid, the galvanometer deflection largely increases. The external resistance is now increased by means of the box, until the deflection is reduced to the same point as at first. This resistance put into the circuit is evidently equal to that of the liquid taken out, and thus a measure of the liquid resistance is obtained. Two forms of apparatus were shown. In one, the vessels containing sulphate of zinc and sulphate of copper respectively, formed pistons in a glass tube which contained the liquid to be examined. In the other, two pairs of concentric vessels were connected by a bent glass tube which contained the liquid under examination. The method is applicable to a great variety of liquids, and with care almost any degree of accuracy may be obtained. The chief obstacle to exact measurements lies in the fact that the resistance of liquids is greatly affected by temperature, but this difficulty is, of course, common to all methods. Mr. Wilson has been experimenting with brine, and gave some of the results obtained, but he has not as yet made a sufficient number of experiments to complete a table. A mode of arranging the apparatus in a differential or bridge form was also described, but it has not been found necessary to use it; the simple circuit arrangement giving accurate results with less trouble. Prof. Foster asked whether experiments had been made in order to compare this method with Wheatstone's, which differed from Mr. Wilson's, as *liquid* electrodes were not used. He then described an arrangement he had adopted for measuring the polarisation of plates in a voltameter. Prof. M'Leod stated that he had used plates of amalgamated zinc and reversed currents to overcome polarisation. He found that some salts, chloride of zinc for instance, had points of maximum conductivity which corresponded to a definite degree of concentration. Prof. Guthrie considered the research to be interesting as showing that points of minimum resistance might coincide with points of definite hydration of the salts.—Mr. Wilson, replying to Prof. Foster, stated tha tthe chief objection to the use of metal plates is not a variation of the electromotive force of polarisation, but the accumulation of bubbles of gas on the metallic surfaces.—Dr. Stone made a communication on the subjective phenomena of taste. He stated that some experiments he had recently made led him to consider whether there might be "complementary taste," just as there is "complementary sight." He described the following experiments as examples of the kind of phenomenon. If water be placed in the mouth after the back of the tongue has been moistened with moderately dilute nitric acid, the water will have a distinctly saccharine taste. Or if the wires from a 10-cell Grove's battery be covered with moist sponge, and placed one on the forehead and the other at the back of the neck, an impression is produced which is exactly similar to that resulting from the insertion of the tongue between a silver and a copper coin, the edges of which are in contact. Dr. Stone showed that the induced current usually employed for medical purposes has not this effect, and he considered the results curious, as, so far as we know, they can hardly be the result of chemical action. Mr. Roberts mentioned an instance in which sudden alarm had been followed by the peculiar taste which results from the introduction of two coins into the mouth, to which allusion had already been made.—Prof. Foster thanked Dr. Stone in the name of the Society, and expressed a hope that he would continue his suggestive and important experiments.—Four other communications were made, of which abstracts will be given in a future number.

Entomological Society, June 7.—Sir Sidney S. Saunders, C.M.G., president, in the chair.—Mr. Briggs exhibited some bred specimens of *Zygæna meliloti*, bearing a strong resemblance to *Z. trifolii*, and mentioned several instances in which the offspring of *Z. meliloti* exhibited a taint of *trifolii* blood, and suggesting that *Z. meliloti* might be only a stunted variety.—Mr. M'Lachlan exhibited a portion of a vine-leaf on which were galls of *Phylloxera vastatrix*, the leaf having been plucked in a greenhouse near London.—The Rev. A. E. Eaton exhibited the insects which he had recently captured in Kerguelen's Island. There were about a dozen species belonging to the *Coleoptera*, *Lepidoptera*, and *Diptera*, besides some specimens of bird-lice and fleas. They were all either apterous or the wings were more or less rudimentary. One of the *Diptera* possessed neither wings nor *halteres*.—Mr. Briggs exhibited a specimen of *Halias prasinana*, which, when taken, was heard to squeak several times distinctly, and at the same time a slender filament projected from beneath the abdomen was observed to be in rapid motion, and two small spiracles close to the filament were distinctly dilated.—The President called attention to a larva which he had recently discovered at Reigate in the body of a stylopised female of *Andrena trimmerana*, the larva having a long telescopic process at the anterior extremity, and two reniform processes behind, similar to *Conops*, an insect which had frequently been reared from *Pompilus*, *Sphex*, and *Odynerus*, and had also been met with in *Bombus*, although he had never before heard of its being found in *Andrena*.—The Secretary exhibited some specimens of a minute *Podura* forwarded to him by the Secretary of the Royal Microscopical Society, having been found on the snow of the Sierra Nevada in California.—Mr. F. H. Ward exhibited some microscopic slides showing specimens of a flea attached to the skin of the neck of a fowl.—Prof. Westwood communicated a description of a new genus of Clerideous Coleoptera from the Malay Archipelago.—Mr. M'Lachlan read a paper entitled "A sketch of our present knowledge of the Neuropterous Fauna of Japan (excluding the *Odonata* and *Trichoptera*)."

Berlin

German Chemical Society, June 14.—A. W. Hofmann, president, in the chair.—The President opened the proceedings by informing the Society that their veteran honorary member, Prof. Wöhler, had very kindly written some recollections of his life for the special purpose of being read to the meeting; refusing, however, their publication in the Proceedings of the Society. The following short extracts of these "recollections of an old chemist" will give some idea of the interest attending the MS. read by the President. On the 2nd of September, 1823, Dr. Wöhler had finished his medical studies at Heidelberg, and, yielding to the advice of L. Gmelin, he abandoned the plan

of practising medicine, took up chemistry as the aim of his life, and repaired to Stockholm as a pupil of Berzelius. Choosing the route from Lübeck by sea, he was obliged to wait six weeks for the departure of a boat. The tedious stay in that harbour was shortened through the acquaintance of a mineral dealer already known to Wöhler from the Frankfort fair, where he had exchanged hyaliths for other minerals, and where Wöhler had met Goethe bent upon a similar errand. He also made the acquaintance of a pharmaceutical chemist, Mr. Kind, at Lübeck, and with him prepared potassium in quantities hitherto unknown in Germany, and which, later on, Berzelius made use of in his studies of boron and silicium. Arriving after a stormy passage, he managed to find his way, by the aid of a Swedish student, with whom he had to talk Latin, the only language they had in common. He trembled almost at the first interview with the celebrated chemist, but was soon put at ease by his genial manner. Berzelius's laboratory was of the simplest. It consisted of two bare rooms and of a kitchen, which served at the same time for cooking the meals of the bachelor-household. This was the time when Berzelius had just adopted the chlorine theory. An old maiden cook who reigned supreme at the hearth complaining one day of the smell of "oxidised muriatic acid," Berzelius exclaimed, smiling, "There is no longer any oxymuriatic acid, Anna; you must say it smells very badly of chlorine." To try his pupil's patience, he put him to the analysis of lievriete, demanding great exactness. When the analysis did not come up to the mark, he said: "Doctor, that was quick, but bad." But soon he took the greatest interest in his pupil's researches on cyanic acid, for which the ferrocyanide of potassium had to be sent for from Lübeck. Berzelius kept his simplicity in his intercourse with the courtiers who sometimes visited the laboratory, and for whom some interesting experiments had to be performed. He was an excellent narrator, and Wöhler listened with the greatest interest to his recollections of Gay Lussac and of Sir Humphry Davy. Wöhler passed a very busy winter, spending his evenings in translating Berzelius' annual reports and Hisinger's treatise on mineralogy. When the spring came he enjoyed walks in the beautiful neighbourhood of Stockholm, studded with the last oaks of the northern zone, and he became intimately acquainted with the Swedish philosophers Caro, Mosander, Retzius, Arfvedson, Hisinger, and others who have now all left the scene of life. At last the time arrived when he had to take his departure from Sweden, and he did so, accompanied by Berzelius himself, who had invited him to take a journey through Sweden and Norway. Many mineral treasures were collected on the road, and the great mines and industrial establishments were visited. At Helsingborg the travellers stopped for several days to wait for the arrival of Brogniart, father and son, the French geologists, and of Sir Humphry Davy. The latter was then salmon-fishing in Norway, and announced his arrival to Berzelius in a letter commencing, "My dear sir and very honoured brother in science." He had some kind and encouraging words for young Wöhler, not forgotten by the latter in his celebrity and his old age. Sir Humphry soon left for Copenhagen, where he had an engagement to shoot snipe with Forchhammer. Oerstedt arrived also to pay Berzelius his respects, and so did several professors from the neighbouring university of Lund. In fact, Berzelius's celebrity was so great that an official in the passport office refused to take any fee from the pupil who had come to study under such a master. Messrs. Brogniart had taken their comfortable travelling carriage over from Paris. Their comfort, however, was disturbed by the arrival of a French courier, the bearer, as they feared, of news of Louis XVIII.'s death. Putting the question to the courier, they received the answer, "Messieurs, vous savez, qu'un courier doit être aveugle, sourd et muet." The journey to Norway was continued in common, the elder Brogniart and Berzelius occupying the carriage of the former, Wöhler and the younger Brogniart following in Berzelius's carriage. They often had to stop all night in their carriages; for it so happened that the Crown Prince preceded them on their road with a numerous suite, and the inns were overcrowded. We cannot enter into the details of this interesting journey. When it came to a close at Helsingborg, Wöhler had to take leave of his master, and the feelings of regret were mutual and deep. Translating Berzelius's reports and his handbooks became henceforth a duty to Wöhler, by which, regardless of the time it demanded, he tried to repay a debt of gratitude. The meeting sent a vote of thanks to the great and modest author of these recollections, praying for his permission to print them in the Society's Reports; and your correspondent hopes he may be forgiven any indiscretion he has been guilty of in preserving for the scientific world these short extracts.

—Th. Zoeller and E. A. Grothe have introduced xanthogenate of sodium as a remedy for Phylloxera. Compared with the sulfocarbonate of sodium, it deserves the preference. $CS\begin{smallmatrix}SNa\\SNa\end{smallmatrix}$ is easily transferred into CS_2 and HS_2, the former killing the Phylloxera, while the latter gas injures the vine; but xanthogenate of sodium, $CS\begin{smallmatrix}SC_2H_5\\ONa\end{smallmatrix}$, cannot produce hydrosulphuric acid, and appears to be by far the better remedy of the two, as well as the cheaper one.—S. Reymann proposes the following way of determining the amount of orcine contained in lichens. Bromine-water of known strength is added to the solution, producing tribromorcine, $C_7H_5Br_3O_2$, until the solution has a permanent smell of bromine. Iodide of potassium is then added, and the amount of iodine set free (corresponding to the excess of bromine added) is determined by volumetric analysis.—The same chemist described an easy method of determining the quantity of bromoform contained in commercial bromine.—E. Donath described a method of extracting from yeast a substance inverting cane-sugar, and called by him invertine.—E. Zuercher has found bromonitroæthan to be transformed by nitrite of potassium and alcoholic potash into yellow needles of potassic dinitroæthan:

$$\begin{matrix}CH_3\\|\\CH(NO_2)Br\end{matrix} + KNO_2 + KOH = \begin{matrix}CH_3\\|\\CH(NO_2)_2K\end{matrix} + KBr + H_2O.$$

The substance resembles the corresponding picrate. The acid is an oily liquid.—E. Forst and Th. Zincke have oxidised the two isomeric glycols, hydrobenzoine and isohydrobenzoine, $C_{14}H_{12}(OH)_2$. Both yield benzoic aldehyde. The authors try to explain the identity of these reactions by constitutional formulæ. —F. Tieftrunk exhibited specimens of gas-tight membranes, invented by Mr. Schülke, and used for a new system of dry-meters by Mr. S. Elster in Berlin. The membranes are not acted upon by hydrocarbons, sulphuret of carbon, or ammonia, and form a much better material for dry-meters than leather. Mr. Tieftrunk demonstrated another application of this invention, consisting in a gas-burner yielding a constant flame. An air-bath heated with this burner did not vary in temperature more than one degree during six hours.

HOLLAND'S "FRAGMENTARY PAPERS"

Fragmentary Papers on Science and other Subjects. By the late Sir Henry Holland, Bart. Edited by his Son, Rev. Francis J. Holland. (London: Longmans, 1875.)

IT is impossible not to be struck with the width of knowledge, the balance of intellect, and the true wisdom shown in the posthumous writings of the late Sir Henry Holland. This distinguished physician was born as long ago as 1788, when many of the most extensive and important sciences—Chemistry, Electricity, Heat, Geology, and others—could hardly be said to exist. Yet we find in these papers that he was fully alive to discoveries which were quite recently made. Not only does he appear to have accepted the Evolution Philosophy in a thorough-going manner, and to have acquired a perfect comprehension of its bearings and results, but the latest discoveries in each branch of physical science were familiar to him, and duly considered in retouching his papers for the last time. Writing in 1873 at the age of eighty-five, he naïvely remarks that it would be impossible at his age to re-write the whole of his essays so as to bring them up completely to the present day. He therefore proposed to select what was most suitable for publication, making such additions as were suggested by the recent progress of research.

The essays, as now published, range over most of the physical and moral sciences, and touch upon theology. The Plurality of Worlds, Creative Power, Matter and Force, Divisibility of Matter, the Nature of Electricity, Animal Instincts, the Perfectibility of Man, Infinity, Eternity, Materialism, Scepticism, Subjective Functions of the Eye, Sleep and Dreams,—such are only a part of the topics upon which he discourses. It is, of course, out of the question that an old man writing between the seventieth and eighty-fifth year of his age could give much that is original and novel upon such a wide range of subjects. Of this he must have been fully conscious, and his object appears rather to have been to sum up the results of the progress of science as he had witnessed that progress, and to point out how far it had really gone in comparison with the possible sphere of discovery. His principal conclusion is, that no efforts of scientific men have yet, or indeed ever can, penetrate the mysteries of existence. His favourite expression is that of Laplace: "Notre ignorance est immense."

He more fully states his convictions in the following words:—

"The horizon of our knowledge continually, though unequally, expands—obscure in its boundary on every side, and ultimately defined by limits impassable to human reason. One man by genius or happy accident may press more closely than another towards this horizon; but the ultimate limit is the same to all, involving those mysteries of matter, force, and creative or governmental power, to which all other problems are subordinate."

One of the most original and interesting essays is that in which Sir Henry Holland treats of "mental operations in relation to time." The same subject had, indeed, been discussed in two chapters of his "Mental Physiology," and he had shown how many striking illustrations of the relations of states of mind in succession, one to the other, may be discovered. He wished to see carried out an experimental inquiry into the chronometry of mind, by observing the velocity with which trains of ideas can be made to move through the mind in various circumstances. The following is an example of the kind of self-experiment which Sir Henry tried (p. 106):—

"Within a minute I have been able to *coerce* the mind, so to speak, into more than a dozen acts or states of thought, so incongruous that no natural association could possibly bring them into succession. In illustration I note here certain objects which, with a watch before me, I have just succeeded in compressing, *distinctly and successively*, within thirty seconds of time—the pyramids of Ghizeh, the Ornithorhynchus, Julius Cæsar, the Ottawa Falls, the rings of Saturn, the Apollo Belvedere. This is an experiment I have often made on myself, and with the same general result. It would be hard to name or describe the operation of mind by which these successive objects have been thus suddenly evoked and dismissed. There is the volition to change; but how must we define that effort by which the mind, without any principle of selection or association, can grasp so rapidly a succession of images thus incongruous, drawn seemingly at random from past thoughts and memories? I call it an *effort*, because it is felt as such, and cannot be long continued without fatigue."

This is a curious subject which easily admits of experiment; but it will be found that the velocity with which thoughts can be made to succeed each other depends entirely upon the degree of similarity or connection between them. Judging from my own experience and that of three students, well qualified to test the matter, I find that where the objects thought of are as incongruous as possible, the number which the mind can suggest to itself in a minute varies from twelve, the result of Sir Henry Holland, up to about twenty. Anyone who tries the experiment, however, will find that there is an almost insuperable temptation to go off on lines of association. To avoid these and yet to think rapidly, requires a very disagreeable effort, becoming more and more painful by repetition.

When the thoughts are restricted within certain grooves, as it were, the result is more rapid succession. Thus one student was able to think in a minute of thirty different kinds of actions, forty-six animals, fifty places, or fifty persons. I can myself think without much effort of thirty-two animals, or forty persons or places in a minute. Even in these cases, however, it will be found that the rapidity greatly depends upon the degree in which the objects have been associated. When thoughts have been very closely and frequently linked together, the number which may be compressed within a minute is much greater. I find that I can count about ninety-six in half a minute, which, without allowing for the two places of figures, gives 192 thoughts per minute. I can think of every letter in the alphabet in five seconds at most, which is at the rate of more than 300 per minute. Finally, by counting the first ten numbers over and over again, I have compressed nearly 400 changes of idea within the minute. Thus it may be said that the facility of mental action varies something like forty-fold, according to the degree of previous association between the ideas.

Little has hitherto been done to investigate the action of mind systematically, but there is little doubt that by

following up the hints given by Sir Henry Holland, Prof. Wendell Holmes, and some others, useful results might be obtained. It is difficult to help agreeing with Sir Henry when he remarks that the opinions of Comte on this subject are a sheer paradox (p. 97). Comte strangely denied the competence of consciousness as an interpreter of mental functions. It may perhaps be allowed that consciousness has not been happily investigated hitherto, but it would be wholly premature to assert that it is incapable of scientific investigation.

W. STANLEY JEVONS

URE'S "DICTIONARY OF ARTS"

Ure's Dictionary of Arts, Manufactures, and Mines. By Robert Hunt, F.R.S., Keeper of Mining Records, &c., &c., assisted by F. W. Rudler, F.G.S., and by numerous contributors eminent in science and familiar with manufactures. Seventh edition, in three volumes. (London: Longmans, 1875.)

THIS well-known work, of which the seventh edition is now before us, first made its appearance in the past generation. During the life-time of its original projector and editor, Dr. Andrew Ure, it undoubtedly contributed largely to advance the education and progress of our manufacturing and industrial classes, and well-thumbed copies of it are to be found on the library shelves of all the "Mechanics' Institutions" which the educational revival of thirty years ago scattered over the land.

We find from the preface that since 1858, when the present editor took charge of the work, three editions, including the present, have appeared, so that its reputation as a standard work of reference appears to be still maintained.

In the volumes now before us, there are, as might be expected, great differences from the edition which preceded them, many new industries having arisen, while others, if they have not altogether disappeared, have at least lost much of their importance. The alterations thus arising have overpassed the space left available by the curtailment and omission of some of the articles which had lost their value, and have increased the size of the work to a total of 3,255 pages for the three volumes. Although a long list of contributors succeeds the preface, we imagine that the burden of the major part of this increase must have fallen on the two editors, and it is therefore with considerable pleasure that we congratulate them on the thorough manner in which the revision has been effected, and the very full and complete information given in nearly all cases. We must not, perhaps, complain if the information given in such articles as "Alizarine" and "Aniline" is not very full, since the complete knowledge of the actual methods of production employed in these and in other cases of chemical manufacture are in the possession of persons whose interest it is not to be very explicit in matters involving manufacturing secrets. While, however, the editors are to be praised for keeping the articles abreast of the time in other respects, we cannot agree with them that it is good policy to retain, as they have done, the old equivalentic formulæ beside the atomic ones which are now, and have been for years past, in such general use as to justify the exclusion of the former altogether, as has been done in every other work on chemical subjects printed within the last five years. The acquisition of the modern views and system of formulæ is really so simple a matter that there is no justification for its not being made by everyone interested in the science, and the retention of both forms tends to confuse young workers while conferring at best a doubtful benefit upon those who, having learnt the older form, are not made to feel the necessity of learning the newer.

As may be supposed from the names of the editors, the parts relating to mining and metallurgy are extremely full of valuable information, and we notice particularly an article on coal-cutting machines, one on safety apparatus for mines, and one on mine-ventilation, as deserving attention. Much information is given on printing, and the mixed chemical and mechanical art of calico printing is most exhaustively treated. In the article on the soda manufacture, a good sketch of Schlœsing and Rolland's process is given. The explanation of the devitrification of glass, given in vol. ii. p. 647, is, however, only probably true in a limited number of cases, in many the change being molecular only, and not involving the formation of definite silicates.

The article on coal-gas is particularly full and well written; but in fact this may be said of so many of the subjects treated that it becomes an invidious task to attempt to point out the shortcomings which are in some cases unavoidable in a work of this magnitude, while it is a pleasant one to congratulate Messrs. Hunt and Rudler on the care and ability bestowed on a task of great difficulty. We have only to add that the type of the work has been entirely reset, and the titles of the articles printed in a bold type which renders reference easy.

R. J. F.

DRUMMOND'S "LARGE GAME OF SOUTH AFRICA"

The Large Game and Natural History of South and South-east Africa. From the Journals of the Hon. W. H. Drummond. (Edinburgh: Edmonston and Douglas, 1875.)

THE countries of Amazulu, Amatonga, and Amaswazi form the tract of land bounded on the south by Natal, and on the west by the Transvaal Republic. These were the scenes of Mr. Drummond's experiences, which, he tells us, extended over a period of some five years, ending in 1872. He candidly admits that his knowledge of Natural History as a science is little or nothing, in consequence of which all reference to questions bearing on the subject are omitted, except those which have come within his personal knowledge. Such being the case, we think that we cannot do better than make an attempt to summarise the direct information which the author places before us on those biological questions which are in any way referred to, leaving the discussion of the many valuable observations on sport in general to contemporaries who are in the habit of keeping those subjects in constant view.

Of the nine chapters which constitute the work, the first six treat of the buffalo, rhinoceros, eland, elephant, lion, and leopard; the remaining three being devoted to anecdotes connected with dogs, antelopes, and game birds.

Respecting the first of these animals, the statement that "only one species of buffalo (*Bubalus caffer*) is found in the southern part of Africa," is confirmatory of the results arrived at by all other investigators. Their abundance and ferocity when charging are much emphasised.

Our knowledge of the African rhinoceroses is much more imperfect than that of their Indian allies, and Mr. Drummond's remarks on these animals must be looked upon as those of a reliable and acute observer. We read: "As far as my experience and inquiries have gone, I believe, in accordance with the recorded opinions of most travellers and sportsmen who have given any attention to the subject, that there are four—two of the so-called 'white,' and two of the 'black.'" The way in which these four species are arrived at, presents one point, at least, of special interest. The first species is the *Rhinoceros bicornis*, "borele" or "upetyane," the smallest and most dangerous of the four, it alone being in the habit of attacking man unprovoked. The second is the *R. keitloa*, the "keitloa" or "umkombe tovote," the next largest, with the hind horn, which is quite small in all the others, very nearly as big as, or even sometimes bigger than, the fore one. In one specimen "the horns, which were unusually good, measured twenty-four inches for the front one, twenty for the back." The third species is the *R. simus*, "umkave," or common white rhinoceros, the largest of all; it is "remarkable for the great length the front horn grows to, as well as for its gentle and inoffensive disposition." With this is united as a variety *R. oswellii*, in which the front horn is particularly long and turns forwards; and we are well disposed to agree with Mr. Drummond in thus laying little or no stress on peculiarities in the horns when they are not associated with other characters. For a knowledge of the last species we have to rely entirely on our author. It has an independent native name, which is in its favour, being known as the "Kulumane." It "differs from the other species (*R. simus*) in three important particulars: firstly, in its horns, which, though following the conformation of *R. simus*, never attain to the same size; secondly, in its measurements, which, while considerably inferior to those of the common white, are greater than those of the other two species, while it is to be noted that it possesses, though in a less marked degree, the long and prehensile upper lip which characterises *R. bicornis* and *R. keitloa*; thirdly, in its food, for though preferring, as was to be expected from the formation of its snout, the young tender shoots and leaves of thorns, it also resembles *R. simus* in consuming large quantities of grass. In its disposition it would seem to combine the characteristics of the other species."

The author was fortunate enough to capture and keep alive for a short time a very young individual of the last-described species, and he tells us that "if a specimen were really wanted for this country [which most certainly is the case], and there is not a single one as yet, I have no doubt that the difficulty of finding a substitute for its mother's milk —a serious one in a land where cattle do not exist on account of the tsetse—might be got over by the sacrifice of the lives of a few cows, for, as the bite of this insect does not cause immediate death . . . they might be brought down to the plains, and would probably live long enough to take the young rhinoceros to the higher districts, where plenty of milk could be procured." It is much to be regretted that Mr. Drummond was not able to employ the method he thus describes so clearly, and so put us in possession of an invaluable zoological treasure.

The light thrown on the question as to whether the striped eland is a species differing from the unstriped animal is but small, the author's experience being in favour of there being but one. Both varieties are met with in Amatonga. As to the elephant, its difference from its Asiatic brother in the conformation of its skull produces an important difference in the hunter's point of view also. In the Indian species "the forehead presents a certain mark, while in Africa it is quite impervious." The following observations will also be read with painful interest. "Slowly, but surely, this most useful animal is being extirpated, merely for the purpose of supplying Europe with ivory ornaments and billiard-balls, and before many years are over the inhabitants of Africa will grieve, when it is too late, at the short-sighted policy which has allowed them, for the purposes of immediate gain, to kill down the only animal capable of becoming a beast of burden through the tsetse-infected districts of that continent." The extreme difficulty of taming the animal, the impossibility of breeding it in captivity, and the rapid advance in steam-locomotive power, must, however, be placed in the balance against the advantages which the creature offers.

The portion of the work devoted to the lion and the leopard abounds in incidents, many of which terminated fatally; so many, indeed, that we can hardly understand how it is that the author places the upetyane (*Rhinoceros bicornis*) before the lion in comparing the different shades of danger encountered from the larger varieties of South African animals.

In conclusion, we strongly recommend this book to all who are fond of sport and who require practical hints on minor details before commencing a similar undertaking. To the student of Natural History it will be equally attractive, because of the clear and pleasing manner in which it depicts the manners and habits of several animals in their native haunts, nothing respecting which can be gained from any amount of study of the dry skins or skeletons. It is by his knowledge of the habits of the creatures which he is accustomed to meet, that the practical naturalist can frequently put the museum-student to shame, and for this reason we think that works like the one before us ought to be studied by zoologists.

Some of the illustrations are good, but many of them are quaint and not always accurate. Why the head of a Zebra introduces the chapter on the Eland, and an Aard Wolf does the same with respect to the Leopard, we are at a loss to understand.

BRUSH'S "DETERMINATIVE MINERALOGY"

Manual of Determinative Mineralogy, with an Introduction on Blowpipe Analysis. By George J. Brush, Professor of Mineralogy in the Sheffield Scientific School. (New York: John Wiley and Son, 1875.)

PROF. BRUSH has endeavoured to make the study of mineralogy lighter than usual, and has in many respects succeeded, but unfortunately for the modern

student he has retained the old chemical formulæ. Surely it would have been better to swim with the times and adopt the new atomic weights, taking care to abolish all doubtful tests, and adding the latest and most accurate methods of analysis. Many of the latest and most delicate methods of mineral analysis are entirely omitted, such as Bunsen's methods for the detection of arsenic, antimony, selenium, molybdanum, uranium, &c. The work in question is divided into two distinct parts; the first containing descriptions of the different apparatus and reagents used, and a "Systematic Course of Blowpipe Analysis;" the second, styled "Determinative Mineralogy," makes use of the knowledge acquired in the first part to determine the mineral species under examination. The "Systematic Course of Blowpipe Analysis" is adapted from the later editions of Plattner's work on Blowpipe Analysis, edited by his successor, Prof. Richter; the "Determinative Mineralogy" is a translation of Von Kobell's "Tafeln zur Bestimmung der Mineralien," tenth edition. Generally speaking, students do not take kindly to "Tables," but Prof. Brush has made them more inviting by arranging the minerals having the same base into groups, and studying them in order. This is an excellent arrangement, and the distinguished author deserves the gratitude of students for thus lightening their labours. Too many mineralogical works of the present day exhibit a harum-scarum kind of classification, which simply bewilders the inquiring student and leaves him in greater confusion than before. The first part of the work opens with descriptions of various kinds of blowpipes, and the manner of using them, also the fuel used to obtain the requisite flame. Here, under the headings "Reducing" and "Oxidising" flames, are described very clearly the characters of the two flames, with very good engravings showing the zones. The methods for preparing the various reagents required are trivial and should have been omitted; for instance, we are told to prepare pure carbonate of soda by taking "four or five ounces of *commercial* bicarbonate of soda *free from mechanical impurities*," &c. We should be glad to know where Prof. Brush obtains his commercial bicarbonate of soda so free from impurity, as the manufacturer deserves encouragement. Chapter II. commences the "Systematic Course of Qualitative Blowpipe Analysis," describing the reactions of the elements and their combinations in the "closed tube and open tube," and on "Charcoal as a support." Under the latter heading a very neat and novel method is given for overcoming the great difficulty experienced sometimes in keeping the assay in its place on the charcoal. Let those who wish to work in comfort for the future buy the book, and find the method therein.

Further on, the colours imparted to a flame by different metallic salts are described, but all of them, with the exception of copper, sodium, potassium, lithium, and calcium, might have been left out with perfect justice, for no one could decide what metal was present from a simple examination of the coloured flame as described; that could only be done by means of the spectroscope. Then follow "The uses of Fluxes and Roasting," and "Fusion with Borax," which are simply adaptations from Plattner, and the tables given in this division are literal translations from the same author, which may also be said of the division "Fusion with Salt of Phosphorus." It is only fair to say that in the preface to his book Prof. Brush states: "The main authorities used in the original preparation and later revision of the chapters on blowpipe analysis were the works of Berzelius and Plattner. The third and fourth editions of Plattner, the latter edited by Prof. Richter, have been chiefly consulted." The whole work seems to confine itself almost entirely to blowpipe analysis by the dry method, ignoring very frequently much easier and quicker methods of detection by the wet method of analysis. A few instances may be given, viz., copper when associated with nickel, cobalt, iron, and arsenic by the dry method, proceed as follows:—"Separate *most* of the cobalt and iron by treating with borax on charcoal, the remaining metallic globule is fused with pure lead, and then boric acid is added; this last dissolves the lead and the rest of the cobalt and iron, while most of the arsenic is volatilised. The cupriferous nickel globule which still may contain a little arsenic is treated with salt of phosphorus in the oxidising flame; the bead obtained will be dark green while hot, and clear green when cold. This last green is caused by a mixture of the yellow of oxide of nickel and the blue of oxide of copper." What a complicated and tedious process! Now let us consider the wet method well known to chemists, but not mentioned amongst the "characteristic reactions" in the first part of this book. Dissolve the mineral in nitric acid or nitro-hydrochloric acid, get rid of the excess of nitric acid, precipitate the copper by means of sulphuretted hydrogen, dissolve this precipitate in nitric acid, and add excess of ammonia, when the liquid at once acquires the splendid well-known blue colour. The arsenic will be present as arseniate of ammonia, and will not interfere with the reaction. Even more easily can traces of copper be detected by Bunsen's neat method, as follows:—Fuse the assay on a charcoal match with carbonate of sodium in the reducing flame, treat the fused mass with distilled water in a porcelain basin, gather together (by means of a small magnet) the metallic particles of cobalt, nickel, and iron, and remove them; dissolve the remaining metallic copper in nitric acid; take up a drop of this solution by means of a glass rod and place it upon a strip of white filter-paper, add a drop of ammonia to the moistened paper, and observe the decided blue colour where the drop of solution was placed. Thus, by the time the student had blundered through the dry method of discovering copper, a skilful chemist would almost have determined the percentage of copper present in the assay by some volumetric process. Singularly enough, the above method is mentioned several times *incidentally* in the second part, entitled "Determinative Mineralogy." Under the heading "Iron," no mention is made of the well-known reaction between ferric salts and ferrocyanide of potassium, but doubtful borax bead reactions are very prominent. The characteristic precipitate obtained by mixing soluble lead salts with bichromate of potassium is omitted also. Chapter IV. opens with "Determinative Mineralogy." These tables are the best part of the book. The student must be very dull indeed who fails to determine a mineral by the use of them. The method of studying the different minerals is excellent, as the specimen under examination is soon brought into a group; and by glancing at the characteristics of each mineral in that group, and com-

paring the reactions obtained with the specimen, the name is ascertained without difficulty. An example will suffice to show this:—"The mineral has a metallic lustre. Its degree of fusibility is 2, and a portion of it is readily volatile, evolving the garlic-like smell peculiar to arsenical minerals. On looking at the tables it is found to belong to Division I. Fused with carbonate of sodium on charcoal in the reducing flame, no metallic globule is obtained, but the reaction for sulphur is seen on moistening the fused mass and placing it upon a piece of silver. Does not give the reactions for copper or cobalt. In the closed tube gives metallic arsenic, and after long heating becomes magnetic. It is found that it can only be one of two minerals, viz., Arsenopyrite (mispickel) or Lölingite. The streaks, colour, and hardness are the same; but two reactions observed before prove it to be arsenopyrite, for it fuses at 2, and gives a strong sulphur reaction." As we have pointed out, it might have been expected that so distinguished a mineralogist as Prof. Brush would have given us all the more modern methods, but, nevertheless, his book is certainly a very useful one, and may be recommended to the student. CHARLES A. BURGHARDT

OUR BOOK SHELF

Elementary Chemistry. By F. S. Barff, M.A. (London: Edward Stanford, 1875.)

THE question which naturally occurs to one on opening this book is, Why was it written? Of late we have had so many books professing to teach elementary chemistry, and some of these really fulfilling their profession, that it is hard to understand why another should be added to the list. In his preface the author says: "This book, as far as it goes, professes to enable the attentive student to acquire a sound knowledge of the very elementary facts concerning the most important of the 'non-metallic elements,' as they are called." Again, he expresses the belief that by the system he has adopted, "boys will have their reasoning faculties strengthened and their powers of observation rendered accurate and acute."

So far as mere facts are concerned, this book appears to to be very trustworthy; the author is evidently well acquainted with his subject; but there is a want of principles to guide the student. If chemistry is to be taught thoroughly, even in its elements, the method of teaching adopted must from the very beginning be a scientific method; it must seek not only to inculcate accuracy of knowledge in detail, but also to point out the generalised expressions which bind together the facts into a connected system. By studying the book before us a boy may certainly gain a considerable amount of good and useful knowledge, but we are afraid that his ideas of what chemical science is will be at best but vague. The author does not appear to have clearly set before himself the end which he desired to secure by writing a book on elementary chemistry. If that end was merely to supply a collection of useful facts about various chemical substances and processes, he has succeeded; but books already existed which supplied this want. If he wished to supply sound chemical knowledge, *so far as the book goes*, he must be said also to have succeeded, but unfortunately he has stopped too soon; the fault is that it does not go quite far enough: a little more carefulness in planning the book, and the introduction of at least a few generalisations to explain the facts, would have added vastly to the value of the book as an elementary educational work. If we compare this little book with others which might be named which cover much the same ground, the want of general ideas to guide the student becomes very apparent. Another question which occurs in connection with a book on chemistry specially intended for the use of boys at school is, Are schoolboys as a rule really interested in this science? Is it found generally advisable to devote any large portion of a schoolboy's time to the study of chemistry; or is it better, when natural science is introduced into a school curriculum, to choose physics as the principal subject-matter for study?

M. M. P. M.

Travels in Portugal. By John Latouche. With Illustrations by the Right Hon. T. Sotheron-Estcourt. (London: Ward, Lock, and Tyler.)

MR. LATOUCHE'S narrative is full of interest and instruction; but why has he not indicated the year or years during which he travelled in Portugal? There is even no date on the title-page. We hope Mr. Latouche will supply the necessary dates in a second edition. The author refers with justice to the general ignorance of Portugal and of its people; many, no doubt, suppose they are a sort of degraded Spaniards, whereas we think it is pretty clear, from the information contained in the work before us, that the Portuguese are in many respects superior to their neighbours. Mr. Latouche evidently knows Portugal well, and has carefully observed the characteristics of its people. In his narrative he wisely gives very few details about the beaten tracks, but describes principally what he saw in districts which are never visited by the ordinary traveller. His work contains much information concerning the people, their ethnology, language, manners, customs, superstitions, and history; about the country itself, its physical features, its natural history, the state of agriculture, and other points of interest. As to the ethnology of Portugal, Mr. Latouche seems to believe that the people are an agglomeration of a greater variety of elements than that of any other country in Europe, and that these elements still remain to a large extent heterogeneous, different elements preponderating in different districts—Celts, Iberians, Phœnicians, Romans, Visigoths, Saracens, Greeks, French, and Jews all contributing their quota. As an illustration of the extensive infusion of Jewish blood throughout all ranks of the people, Mr. Latouche tells the following anecdote:—"When that foolish bigot, King Joseph, proposed to his minister Pombal that all Jews in his kingdom should be compelled to wear white hats as a distinctive badge, that sagacious minister made no objection, but when next he appeared in Council it was with two white hats—'one for his Majesty and one for himself,' explained Pombal, and the King said no more about his proposal." With regard to the natural history of Portugal, Mr. Latouche thinks there is much still to be learned; that, in fact, it has been less studied than that of any other country in Europe. There is no doubt much truth in this, but we hope it will not be necessary for any foreign "patient naturalist" to learn the language, as Mr. Latouche suggests, in order to investigate the natural history of Portugal. Surely there is a sufficient number of competent men in the country itself to undertake the task, if their attention were directed to the importance of having it accomplished. Indeed, we believe there have not been wanting signs recently of an awakening of intellectual life in Portugal, and we hope that one of its results will be a thorough investigation of the natural history of the country, as well as a vast improvement in the wretched system of education which prevails. The Portuguese, as our readers know, were at one time one of the most enterprising people in Europe, and under proper guidance might still occupy an honourable position among the nations.

To those who wish to obtain some trustworthy information concerning the present condition of Portugal, we commend Mr. Latouche's work, which, we may state, is enlarged from a series of articles which were published in the *New Quarterly Magazine.*

Temperature of the Body in Mountain Climbing

I HAVE read with great interest the able paper on the Temperature of the Human Body during Mountain Climbing in NATURE, vol. xii. p. 132, and as it is there mentioned that the results obtained by Drs. Marcet and Lortet require confirmation, I am tempted to send some extracts from notes of observations made on myself while on a walking tour last autumn, in the Yorkshire moors. I made in all five ascents, of heights over 2,000 feet, during all of which I took notes of my temperature at intervals. As, however, I had no more than a hearsay acquaintance with Dr. Marcet's results, and was not aware of the important influence of the act of ascending as distinguished from the elevation attained, my earlier results were not sufficiently connected to be worth publishing. Suffice it to say that I always obtained a fall of from one to two degrees. On the fifth day of observation, when I was alive to this and other sources of error, I made the following observations in the course of the ascent of Whernside and Gragreth.

	Time.	Height in feet.	Temperature in mouth.
In bed, Chapel le Dale, feeling warm	7.30	900	97·7
Breakfast	8.30	—	—
Before starting, feeling cold	9.40	—	97·6
Walked one mile nearly level; spent half an hour at Gate Kirk Cave, then a steep ascent; after rising 1,000 feet and while hot, tired, and sweating, and before stopping	11.20	1,900	96·4
Sat down; after ten minutes' rest felt fresh, and neither hot nor cold	11.30	—	98·2
Ascent continues steep till near the top, when it is moderate; reached the top hot, sweating, and out of breath; temp. of air 47°, barometer 27·4 in.	12	2,414	97·6
After sitting still in a cold wind and eating 4 oz. biscuits; toes and fingers cold, and shivering slightly	12.37	—	99·3
Steep descent of 1,000 feet, came down at a run; fingers and toes getting warm; before stopping	1.10	1,400	98·0
Crossed the valley to ascend Gragreth; after climbing 500 feet, sweating and feeling hot, and before stopping	2.17	1,900	96·4
After sitting seven minutes	2.24	—	97·6
Still sitting, feeling cooler	2.29	—	98·6
Still sitting	2.33	—	98·6
Nearly at the top	2.47	2,200	98
On the flat top of Gragreth, going slower, feeling cooler	2.52	2,250	98·2
Sitting, feeling cold, strong wind...	3.12	—	98·4
After descending 1,050 feet rapidly	3.55	1,200	98·4
After sitting ten minutes...	4.5	—	98
Sitting warm, at "George and Dragon" Inn, Dent...	9.50	500	97·9

In comparing the temperatures above it should be borne in mind that I uniformly found my temperature in bed in the morning 97·6 or 97·7, and about the same at 9 or 10 at night; while the day previous, when detained in the house by bad weather, it had been 98·4 and 98·6 in several observations, between 10.30 A.M. and 6 P.M., and this I have found the case on many other occasions, so that the difference between the second and third observations really represents a greater depression than is apparent.

It is worthy of note that the two lowest temperatures, viz., 96·4, both occurred during steep ascents and before stopping, and while I was perspiring freely and feeling hot. In each case I immediately sat down and noted a progressive rise in the temperature, though at the same time I was feeling much cooler. When I began to shiver from sitting above half an hour in a strong wind on the top of Whernside the temperature had actually risen to 99°·3. This reminds one of the cold stage of ague, when a patient may have a temperature of 105° while his teeth are chattering with cold.

I entirely agree with Dr. Marcet that it is the fact of actively climbing and not the actual elevation, which influences the temperature. When sitting quiet on the top of Whernside and Gragreth the temperatures were at or above the normal. The steepness also appears to have great influence; both these mountains have flattish tops, and the temperature on reaching the top of Whernside shows less depression than during the ascent, while that taken walking on the flat top of Gragreth, though without stopping, after the ascent showed scarcely any.

I noticed no depression of temperature in descending, though I often came down at a run, and none in several long level walks.

And now as to any possible fallacies. The same thermometer was used in all the observations. It is a Philips' maximum, by Wood and Co., of York, is graduated in fifths of a degree, and easily reads to tenths. I have compared it with a thermometer certified at Kew, and find it very exact. It rises to within a degree of the truth in ten seconds after putting under the tongue, and I am accustomed to rely on its indications after being in about two minutes. In all the above observations it was left in the same position under the tongue five minutes by the watch (except the reading at 2.33, when it was only four); consequently any failure to rise to the true temperature would be likely to affect all the readings nearly alike. Whatever error may be due to this cause would be likely to show itself in raising the readings during the ascents, as at these times the heart was beating strongly and the circulation particularly active; so that the cooling of the mouth by the cold bulb would be quickly neutralised. I was also particularly careful not to allow any air to enter through the lips and as little as possible through the fauces, and feel confident that there is no appreciable error from this cause.

As to the *rationale* of the process, may not the following theory embrace all the facts as observed by Marcet, Forel, and others?

Heat motion and chemical force are merely varieties of one force convertible under certain conditions. The human body is an engine, in which muscle and other tissues are oxidised, and the resulting chemical force is transformed into an equivalent amount of motion and heat. Now it is manifest that there is a limit to the rate at which oxidation can go on in the body, and consequently to the amount of force available for transformation in an unit of time into motion and heat. Usually the human machine is not worked up to its full power; the amount of motion produced is nothing approaching what is possible, and only sufficient force is transformed into heat to keep the body at the normal temperature of 98·4; but in the limit the two processes become complementary to each other, and if from any cause the force converted in one direction exceeds a certain amount, the excess can only be obtained at the expense of what would ordinarily be converted in the other. Now, in mountain climbing the amount of motion as expressed in foot-pounds of work done is very great, and much exceeds the amount to which most of us are accustomed in walking on a level road. If this be pushed to the limit it encroaches on the amount of force destined for the supply of heat to the body, and the temperature falls. It is clear that these processes habitually go on at different rates in different individuals; if so, may not the limit of the rate of tissue change be different? One man may be able to push his motion production nearly to the limit up to which his oxidation will work, thereby encroaching on what ought to sustain his temperature, while another, whose muscles are less fully under the dominion of his nerves, or whose power of oxidation is considerable, may be unable to reach that limit.

To this class I believe Dr. Forel to belong; in the other, the slow oxidisers, I find myself in the honourable company of Drs. Marcet and Lortet. TEMPEST ANDERSON

Trevandrum Magnetic Observations

THOUGH I have felt much gratified with the notice by Prof. B. Stewart of the first volume of the "Trevandrum Observations" which appeared in last week's NATURE, p. 163, I desire, nevertheless, to make a few remarks on the only point on which we appear to differ.

There are two methods of investigating the laws of magnetic disturbance, which have quite distinct objects; one, which has been employed with much success by that eminent veteran of science Sir E. Sabine, seeks, as he has expressly stated, the laws of the *larger* disturbances only, and for this end chooses only those deviations from the mean positions that are greater than some arbitrary value. The other method seeks the laws of disturbances of *all* magnitudes, and employs deviations of *all* amounts.

As Prof. Stewart regrets that I have employed the latter method, and suggests that the former may yet be used by others,

it may be supposed that the laws of disturbance are not found by me, and are not to be found by the method which I have employed. This would be a great mistake; one which I am bound to correct.

The method which Prof. Stewart recommends has had objections proposed to it by the Astronomer Royal, the Provost of Trinity College, Dublin, and by myself. It is, I think, to defend the method against these objections that Prof. Stewart has written his remarks on the modes of discussion; but I have never heard any objections to the other method, nor, as far as I can understand, does he offer any.

As the method followed by Dr. Lloyd on the Dublin Observations and by myself on the Makerstoun and Trevandrum Observations has shown every law of magnetic disturbance that has been obtained by the other, I am afraid I cannot see that the illustration of the cyclones is applicable to the two methods, even if we were bound to study large cyclones only and to put those of less than a given magnitude out of consideration.

Anomalous Behaviour of Selenium

IT has been lately observed that the electrical resistance of selenium is greater in the light than in the dark. It was at first thought possible that this increase of resistance might be due to heat admitted with the light, but Prof. W. G. Adams, in his paper read before the Royal Society, June 17th, 1875, has shown that this is not the case, but that the phenomenon is a purely optical one.

The writer of this letter has to-day tried an experiment with a selenium bar belonging to the Cavendish Laboratory. Its length is 50 mm., breadth 8 mm., thickness about 1 mm.; platinum wires are soldered to its ends, and it has a hard metallic surface. Its electrical resistance is enormous. In the dark it is just over 100 megohms (100,000,000 B.A.U.) When, however, the light of the paraffin lamp of the galvanometer was allowed to fall on it from the distance of about a foot, the resistance DECREASED between 20 and 30 per cent. The experiment was repeated many times, with current sent sometimes one way, sometimes another, and with different sides and edges of the bar turned to the light, but always with the same result, namely, that the effect of letting in the light was to largely *decrease* the resistance.

A second set of experiments were made with a selenium medal struck by Berzelius soon after the discovery of the metal in 1818, and presented by him to Mr. Deck, by whose son, Mr. Deck of Cambridge, it was kindly lent for the experiment. This medal was of oval shape, about 40 millims. long by 30 broad. Owing to the difference of form between the two specimens, their specific resistances could not be accurately compared; that of the medal was, however, not more than about $\frac{1}{10}$ of that of the bar. The medal was exactly like black lead both to touch and sight, and quite different in appearance to the bar. The resistance of the medal *was sensibly the same, both in the dark and in the light; no difference could be detected.*

These experiments seem to show that the physical form of the metal has a great deal to do with its behaviour when carrying an electric current and exposed to light.

The House-fly

As no one more competent than myself seems disposed to reply to the query of "Harrovian" (NATURE, vol. xii. p. 126) respecting a disease of the house-fly, and which is again referred to by the Rev. D. Edwardes in last week's NATURE, I may perhaps be permitted to make a few remarks thereon.

I have frequently noticed dead and dying flies thus affected, generally in the late summer and autumn; and I think I am right in attributing the phenomenon to the growth of a parasitic fungus, called, I believe, *Empusa musci*, in the fly's body. The insects may often be seen settled in a natural position on window-panes, but with the abdomen much distended, and surrounded by a collection of whitish powder, extending for a few lines in all directions on the surface of the glass. The whole of the interior organs of the abdomen are consumed by the plant, nothing remaining but the chitinous envelope, on which the mycelia of the fungi form a felt-like layer; the fructification showing itself externally as filaments protruding from between the rings of the body.

Insects are very subject to the attacks of such parasites. Some of those living in the interior organs of the body seem to do little if any injury to their "hosts," while others completely destroy them; as in the case of *Sphæria*, which changes the caterpillars at whose expense it lives into a mass of fungoid growth of most grotesque appearance. It is now well ascertained that a species of *Botrytus* produces the dreaded "Muscardine" of the silk-growers; and every practical lepidopterist has had to lament the destruction of pet broods of larvæ by some similar disease, which, though perhaps sometimes pathological, is probably in the first instance set on foot by fungi.

The whole subject of the parasites of insects is extremely interesting. According to my experience it is the exception for an insect to be quite exempt from the attacks of one or more animal or vegetable entozoic or epizoic organism; and I have often found five or six different species inhabiting one unfortunate individual.

I may mention that "Harrovian" will find some remarks on this fly-fungus by Dr. Cohn, in an early volume of the *Journ. Micros. Science.* I regret that, writing away from home, I cannot give the exact reference. W. COLE

Stoke Newington, N., July 2

[We print this letter from among several which all correctly explain the phenomenon under consideration in a similar manner.—ED.]

Theories of Cyclones

IN NATURE, vol. xii. p. 98, you notice a paper by Dr. Hann on two rival theories of cyclones. According to one, "whirlwinds are formed mechanically by different streams of air meeting, and centrifugal force causes the central depression. The more modern theory regards a local depression as the first condition, causing an indraft resulting in a whirlwind through the earth's rotation: the primary depression is held to follow condensation of vapour."

The question is how the cyclone begins: whether the first depression is due to the centrifugal force of an eddy, or to the expansion of air in the upper strata from the heat liberated in the condensation of vapour. There need not be any controversy as to the dynamics of the cyclone after it is formed.

There is a mass of geographical evidence in favour of the first-named theory, namely, that cyclones originate in the conflict of the trade-winds of the northern and southern hemispheres when either trade-wind is drawn to some distance across the equator. (A cyclone cannot be formed on the equator, because there the earth has no rotation in relation to a vertical axis). On this subject see Mr. Meldrum's paper in NATURE, vol. ii. p. 151, and my letter in NATURE, vol. iv. p. 305; also Mr. Maury's paper in NATURE, vol. viii. pp. 124, 147, 164.

Mr. Maury fully recognises the truth that the motive power of the cyclone, once it is formed, consists in the heat liberated by the condensation of vapour, which causes expansion in the upper strata and produces an ascending current. I believe the nature of these actions was first explained by Espy, whose "Philosophy of Storms," though well known by name, seems to be less appreciated than it deserves.

There is, however, another reason for the existence of an ascending current at the centre of a whirlwind, which I do not think I have seen stated. The lowest atmospheric stratum of a whirlwind is retarded in its motion by friction against the earth, and its centrifugal force is thereby lessened in proportion to that of the upper strata. The effect of this relative deficiency of centrifugal force in the lowest stratum—that is to say, at the surface of the earth—must be to cause a flow of air at the surface of the earth towards the centre of the whirlwind, and an ascending current at its centre. Such an ascending current is probably the cause of the vertical columns of dust that accompany those small whirlwinds which are common in windy weather.

Co. Antrim, June 23

The Dark Argus Butterfly

IT is stated in H. N. Humphrey's work on "British Butterflies," that the Dark Argus Butterfly appears in July, and has only been found in the neighbourhood of Durham and Newcastle, and seldom above half a mile from the sea. When in May I was at Ashmore, which is on the borders of Dorset and Wilts, I took some butterflies answering exactly to the description of

the Dark Argus in Mr. Humphrey's book; so would you kindly inform me whether this is a new locality, and whether there are two broods, the first in May and the second in July, as is the case with several of family, as would appear from the above statements? I identify the species with his Dark Argus by the following peculiarities, viz.: (1) an obscure black spot near centre of fore-wings; (2) *no* black spots in the orange ocelli in fore-wings, the hind-wings containing these black spots as in the Brown Argus. JOHN HODGKIN, JUN.

West Derby, near Liverpool

Meteorological Phenomenon

WHILE walking out yesterday afternoon my attention was drawn to a very remarkable display of mares-tail clouds spreading from the north, stretching in broad and narrow bands in every direction over the whole sky, and reaching beyond the zenith. While standing thus facing the sun, I saw, at a great elevation, a coloured bow with its convex red side towards the sun; it was only about one-sixth or one-seventh of a circle, and its width seemed to be only about half that of an average ordinary rainbow. It had the appearance of being nearly horizontal, with its centre not far from the zenith, but probably not so distant. Not being accustomed to estimate elevations, when I got home I took a quadrant and held it about the elevation of the part of the bow nearest the sun, and found it came out, on repeated trials, at a *zenith distance* of 25° or 26°.* When I first saw the bow it was just 6h. 30m. P.M. Greenwich time, and the sun appeared to be about 15° above the horizon (that you can correct by calculation). The sun was shining brightly, and the bow was projected over a patch of sky slightly dimmed, at a great height (but below the cirri?), by a smoke-grey haze; its ends just projected over the edges of the clouds. It lasted about 2m. and then faded away. There was no halo or ring but this. The wind was a rather fresh breeze, between S.S.E. and S.

Norwich, June 28 HENRY NORTON

* Subtended at my eye by bow and sun = about 50°?

OUR ASTRONOMICAL COLUMN

SÛFI'S DESCRIPTION OF THE FIXED STARS.—The author of the ancient Uranometria to which we adverted last week, Abd-al-Rahman al-Sûfi (an abbreviation of a much longer name), was born in 903; he was of the sect of the Sûfis, and of Rai, a place to the east of Teheran. He was in high favour with Adhad al-Davlat, of the reigning family of Persia, and it was principally for the instruction of this prince that he wrote the work under notice, which was not the only one he produced. Ibn Jounis reports that he was not only an observer, but framed astronomical tables; and Dr. Schjellerup states he is known to have undertaken geodetic operations. He is said to have determined the length of the year, and in his tables fixes the mean motion of the sun in the Persian year at 359° 45′ 40″·2. He died in May 986. The prince Adhad al-Davlat, who gave great encouragement to the study of the sciences, commenced his reign in 949, and at the time of his death, in 983, governed the extent of country situate between the Caspian and the Persian Gulf.

The translation of the "Description of the Fixed Stars" by Sûfi was made by Dr. Schjellerup from a manuscript preserved in the Royal Library at Copenhagen, which came into the possession of Niebuhr in 1763. It is a copy made in 1601 from a manuscript transcribed in 1013, and, as stated by Schjellerup, "directement d'après l'exemplaire de Sûfi." The translation was finished when the Danish astronomer, through Herr Dorn, had the opportunity of consulting another copy of Sûfi's work, recently acquired by the Imperial Library of St. Petersburg. Where differences exist between the two authorities, they are particularised in notes to Schjellerup's translation.

The description of the stars by Sûfi, though founded upon that of Ptolemy, is not merely a simple translation. All the stars contained in Ptolemy's catalogue were sought in the positions there recorded, and submitted to attentive examination, and their magnitudes carefully noted, as is distinctly stated by Sûfi in his preface. Schjellerup draws attention to the great extent of his work, the perseverance displayed, and the minute accuracy and scientific criticism with which the whole is executed; so that, under all circumstances, the Persian astronomer has presented us with the state of the sidereal heavens in his time, which merits the highest confidence, and which during nine centuries remains without a rival, not having found its equal till the appearance of the "Uranometria Nova" of Argelander.

Prefixed to the description of the constellations, Schjellerup has published what he terms "Tableau synoptique de l'intensité lumineuse des étoiles principales selon Ptolémée (ou Hipparch), Sûfi et Argelander," which is obviously a valuable compilation, and one that may be frequently consulted in cases where the naked-eye stars are suspected of variability. The magnitudes attributed to Ptolemy are not those given in our editions of the "Almagest," but are taken from the work of Sûfi; indeed, Schjellerup considers the former "parfaitement inutiles," being expressed in round numbers and with much confusion, so that in this respect also we have an important addition to our knowledge of the magnitudes of the stars.

In Sûfi's tables of positions, the longitudes of the Almagest are increased 12° 42′, the latitudes being unaltered.

Generally speaking, there is a fair agreement between the magnitudes of Ptolemy and Argelander, the differences not often exceeding a degree of the scale. Amongst the larger discordances Schjellerup points to the cases of 25 Orionis and ρ Eridani, estimated by Ptolemy of the third and fourth magnitudes respectively, while by Argelander they are called a bright fifth and a sixth. Sûfi's estimates in the middle of the tenth century are intermediate, the first star being rated a fourth and the second a fifth magnitude. The case of Sirius is worthy of attention for another reason. Cicero, Horace, and other classical writers refer to the ruddy colour of this star. In the editions of Ptolemy it is indicated as ὑπόκιῤῥος, but Sûfi makes no mention of this reddish tinge, though, as was stated last week, other stars well marked as red stars in our own day, are also so distinguished in his description of the heavens. Instead of reading with Halma καὶ ὑπόκιῤῥος, Schjellerup thinks we should more correctly read καὶ σείριος, conformable to the designations which Ptolemy gives to the other bright stars which bear a proper name, as with α Bootis (ἀρκτοῦρος), α Leonis (βασιλίσκος), &c.; and remarks that it is certain Cicero was the first who mentions the ruddiness of Sirius, that Horace followed him, and that after Seneca we find no reference to it. Eratosthenes, Aratus, Manilius, Hyginus, and Germanicus are silent as to this particularity of the star.

The great nebula in Andromeda is named by Sûfi as an object generally known in the heavens, and it is interesting to note that he also records the variable star recently detected by Herr Julius Schmidt near α Virginis. Its position is very clearly described.

The title of Schjellerup's translation is "Description des Étoiles Fixes, composée au milieu du dixième siècle de notre ère, par l'Astronome Persan Abd-al-Rahman al-Sûfi, par H. C. F. C. Schjellerup, St. Pétersbourg, 1874." It was presented to the Imperial Academy in June 1870.

SOLAR RADIATION AND SUN-SPOTS

SINCE I communicated to NATURE the first results (vol. xii. p. 147) of an examination of the Indian registers of solar-radiation temperatures, I have examined some other registers, all of which confirm the conclusion adumbrated in my former note. Among these the most interesting and striking is the hill station Darjiling, in Sikkim, nearly 7,000 feet above the sea. The place is very cloudy, being on the outer Himalayan range, and much

exposed to the moist southerly winds, but it has two advantages over the stations in the plains, viz., that there are nearly 7,000 feet less atmosphere above it, and it is free from the dust haze, so prevalent on the plains, which perhaps more than water vapour (if not thickly condensed) stops a large part of the solar radiation. On clear days and in intervals between the clouds, the sun's heat is sometimes very intense. The table that follows has been compiled in a different manner from that which I communicated a fortnight since. Instead of picking out days with little or no cloud (which are sure enough during the greater part of the year), I have taken the three highest recorded sun-temperatures in each half-month, and from these have deducted the maximum air-temperatures recorded on the same days; the mean of the six observations being taken to represent the month. The same instrument has been in use since the observations were commenced in April 1870. I must leave it to meteorologists at home to compare these temperatures with the recorded sun-spot areas, which I am unable to ascertain. But the maximum radiation temperature evidently falls in 1871, the year of maximum spots, and the increase on that of the imperfect year 1870, and the fall in the subsequent years, at least up to the end of 1874, are very marked.

Mean differences of the three highest solar temperatures in each half-month and the corresponding maximum air temperatures at Darjiling.

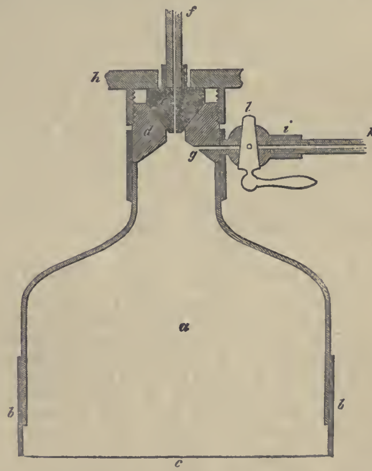
In my former note I adverted to Prof. Köppen's results on the variation of the temperature of the lower atmosphere in the tropics, which he showed to be inversely as the number of the sun-spots or nearly so, from 1820 to 1858. On thinking the matter over, this result, however anomalous at first sight, appears to me really only in conformity with what might be expected when taken in connection with the facts of the rainfall. Since three-fourths of the earth's surface are covered with water, the chief effect of increased radiation must necessarily be to increase the evaporation, and therefore the cloud and rainfall. The former of these will intercept a larger proportion of the solar heat and prevent its reaching the ground; while the latter, by its evaporation from the land surface, will still further reduce the temperature. The annual curves of temperature at the Bengal stations show most strikingly how the temperature falls with cloud and rain. A single heavy storm without any change in the prevalent wind direction reduces the temperatuie by several degrees for two or three days after the fall; and the same fact is illustrated in the mean annual curve, which falls considerably on the setting in of the rains, while there is generally a slight rise in September when the rains draw to a close. It follows, then, that the whole increase of the sun's heat and something more, in the tropics, is absorbed in evaporation and by the upper strata of the atmosphere, thus affording a confirmation of the speculation of (I think) Sir John Herschel, that the inferior planets (if partly covered by water) may enjoy an equable moderate temperature fitted for the existence of such terrestrial organisms as can thrive under a sombre sky.

June 7 H. F. BLANFORD

SCIENCE IN GERMANY

(*From a German Correspondent.*)

BUNSEN'S ice-calorimeter was used lately for a very interesting experiment by Messrs. Röntgen and Exner, who tried to determine the intensity of the radiation of the sun by means of an apparatus constructed on the principle of that calorimeter. The apparatus consists of a glass bell *a* of 75 mm. height. This is fastened into a brass hoop *b*, which is closed below by a plate of wrought silver of ¼ mm. thickness, and 106 mm. diameter. The neck of the bell bears a massive brass top *d*, which is cut conically above and below, and has a central opening of 6 mm. diameter. Into the exterior groove a massive brass cone *e* fits water-tight, having also the central boring, into which a little glass tube is fastened. By a screw *h* in the circumference, the cone *e* can be firmly pressed against the brass piece *d*, while the tube *f* communicates with the interior of the bell *a*. A second communication between the interior of the bell and the



outside is obtained by the boring at *g* and the metal-tube *i*, with stopcock *l*.

When the apparatus is to be used as a pyrheliometer, the bell is filled with well-boiled distilled water, and the whole is frozen like one of Bunsen's calorimeters. To the tube *f* a long glass tube of perfect calibre and with millimetre divisions is fastened by means of a piece of india-rubber tubing; to the end *k* of the brass tube with stopcock an indiarubber ball filled with well-boiled water is then fastened, the stopcock opened, and while the apparatus is held vertically, all air which may still be contained in the bell is removed from it through the cone *e*, the tube *f*, and the divided tube, so that the latter is filled with water up to its end. Then the stopcock *l* is closed. If beforehand the silver plate has been carefully covered with soot, the apparatus is ready for use. It is directed towards the sun just like Pouillet's pyrheliometer, so that the sun's rays fall vertically upon the blackened plate. The divided tube is then supported as much as possible in a horizontal position, and the progress of the column of water in the same is observed with a second clock from minute to minute. This progress of the

column of water would indicate directly the intensity of the radiation of the sun in calories if the ice did not also partly melt in consequence of the surrounding warm air. In order to eliminate this influence, the progress of the column of water must be observed before and after the actual experiment, and during these observations the sun's rays must be shut out from the apparatus by a screen. The difference of the readings with and without the sun's rays will then indicate the density of the latter. But this method has a drawback. It was found that with experiments which were made in quick succession, when the apparatus was exposed to the sun's rays, that the first results were always a little larger than the following ones, and that only after some time had elapsed did the results show a constant value. The reason of this is doubtless the formation of a stagnant layer of water in the apparatus below the blackened plate, and this layer must first reach a stationary position before anything like regularity is obtained in the results.

With regard to the general results of these experiments, which were made by Messrs. Röntgen and Exner on the platform of Strassburg Cathedral, the absolute values of the intensity of the radiation of the sun are considerably larger than those found by Pouillet. If Pouillet's values are reduced to the same measures and units, which form the basis of the values obtained by Röntgen and Exner, we find, for instance, for the month of June and the sun's elevation 12h. the value 1·140, while the latter observers still obtained 1·226 for an elevation of 12h. 15m. Further, we must remark that the values obtained by Röntgen and Exner are decidedly too small (the observations record the progress of the column of water after the stationary condition of the stagnant layer of water), and that according to a rough guess they should be at least 20 per cent. to 25 per cent. larger; thus it is certain that Pouillet's values must be looked upon as *considerably too small.*

*FERTILISATION OF FLOWERS BY INSECTS**

XI.

Adaptation of Flowers to Lepidoptera—Hesperis tristis.

LEPIDOPTERA are distinguished among all insects that visit flowers by their slender proboscis. Hence, in order to make their honey exclusively accessible to these insects, flowers have only to narrow the entrance to their nectaries to such a degree that no other proboscis but that of Lepidopterous insects is able to enter. This adaptation to butterflies by narrowing the entrance of the nectary in different families of plants has been

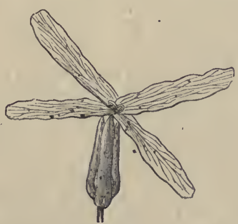


FIG. 65.—Flower of *Hesperis tristis* (natural size).

arrived at in very different ways. In flowers with a tubular corolla (*Primula villosa*, *Daphne striata*, NATURE, vol. xi. p. 110, Figs. 43-47) the corolla-tube has narrowed; in flowers with a honey-secreting spur (*Gymnadenia*, *Nigritella*, NATURE, vol. xi. p. 170, Figs. 58-62) the entrance of the spur has been constricted; in the labiate flowers of *Rhinanthus alpinus* (NATURE, vol. xi. p. 111, Figs. 51-56) the large entrance of the flower is blocked up by the margins of the upper lip lying close together, and only a small opening in its rostrate projection has been left open; in the quite open flowers of *Lilium Martagon* (NATURE, vol. xii. p. 50) the honey-secreting furrow at the base of the sepals and petals has been converted into

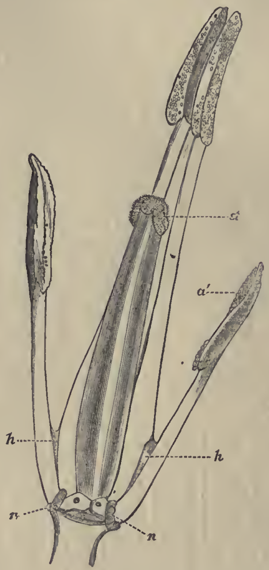

FIG. 66.

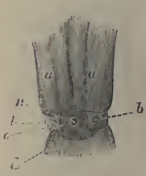

FIG. 67.

FIG. 66.—The same after the sepals, the petals, and two of the four longer anthers have been removed. *n*, nectary; *h*, honey; *a'*, shorter anther; *st*, stigma.

FIG. 67.—Situation of the nectary. *a a*, longer filaments; *o*, point of insertion of one of the shorter filaments; *b b*, points of insertion of the two adjacent petals; *d*, insertion of the adjacent sepal; *n*, nectary.

a narrow channel by a coating of glandular hairs. *Hesperis tristis*, belonging to the family of Cruciferæ, which are generally visited for honey by Apidæ, Syrphidæ, Muscidæ, and various other insects, has excluded from its honey all visitors except Lepidoptera, by simply lengthening its sepals and the basal portion of its petals and laying them close together. The sepals, indeed, as is shown by Fig.

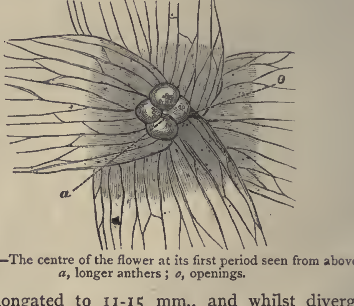

FIG. 68.—The centre of the flower at its first period seen from above. *a*, longer anthers; *o*, openings.

65, are elongated to 11-15 mm., and whilst diverging and presenting open slits in their basal portion, are convergent and connate towards their tips. By this coalescence of the sepals the entrance of the flower is so constricted as to be almost completely filled up by the four longer anthers (*a*, Figs. 68, 69). At first, when the

* Continued from p. 50.

flower has just opened, only a single very small opening is commonly left free (*o*, Fig. 68); somewhat later, when the longer anthers have advanced a little further, two small openings are frequently obvious (*o o*, Fig. 69), by which Lepidoptera can insert their proboscis. The exclusion, however, of all other insects from the honey would be useless or even fatal to this, as well as to the above mentioned flowers, unless by particular contrivances, (1) increased frequency of the visits of Lepidoptera,

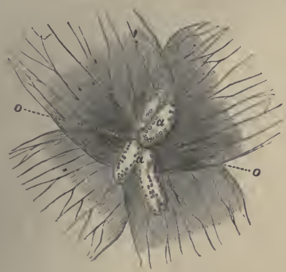

Fig. 69.—The same, at a somewhat later period.

and (2) certain cross-fertilisation by them were effected. *Hesperis tristis*, by the very inconspicuous colour of its flowers, which are yellow reticulated with purplish streaks, by opening them in the afternoon, and by having no smell in the daytime whilst very fragrant towards the evening, proves to be adapted exclusively to crepuscular and nocturnal Lepidoptera, which, attracted from afar by the sweet odour, are induced to pay frequent visits. The base of each of the two shorter filaments is surrounded by a greenish swelling (*n*, Figs. 66, 67), which secretes on its inside honey so copiously that it rises in the interstice between the shorter and the two adjacent longer filaments. Cross-fertilisation by the visits of moths is secured in the following manner. From the one or two small openings (*o*, Figs. 68, 69) the proboscis of the moth is guided downwards by the longer filaments as in a channel, first along one side of the stigma (*st*, Fig. 66), which has bent downwards on both sides just into the way of the proboscis, then

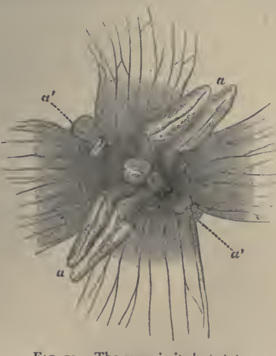

Fig. 70.—The same in its last state.
(Figs. 66–70 are seven times magnified.)

along the shorter anther (*a'*, Fig. 66), which from the other side has turned its pollen-covered front likewise exactly into the way of the proboscis, until at last it reaches the honey (*h*, Fig. 66); the proboscis afterwards wetted with honey at its tip, when retracted, first touches again the anther *a'* with one side, which is thus charged with pollen, then with the other side the stigma, which thus escapes fertilisation with its own pollen, and when in the next visited flower the tip of the proboscis with its pollen-charged side touches the stigma, cross-fertilisation is effected.

My daughter Agnes, perseveringly watching *Hesperis tristis* during several mild evenings in the month of May, has succeeded in observing and catching the following fertilisers of it:—(1) *Plusia gamma*, frequently (length of the proboscis 16-18 mm.); (2) *Hadena sp.* (11 mm.); (3) *Dianthœcia conspersa*, W.V., twice (13 mm.); (4) *Iodis lactearia*, L.; (5) *Botys forficalis*, L., three times.

But although in calm and warm evenings, as is proved by these observations, cross-fertilisation may be sufficiently effected; yet in unfavourable weather all flowers of many individuals develop and fade without experiencing any visit of fertilisers. In this case, nevertheless, almost every ovary develops and brings to maturity its seed-vessels, self-fertilisation being regularly effected by the pistil growing and the stigma coming into contact with pollen-grains of the four longer anthers.

Thus, in these flowers the four longer anthers have apparently no other function in the first period of flowering but to exclude incompetent visitors from the honey, by stopping the entrance of the flower, and, by the direction of their filaments, to keep the proboscis of the fertilisers in the right direction, whilst in a later period, in case visits of moths have been wanting, they regularly effect self-fertilisation. The two shorter anthers, on the contrary, are exclusively adapted to cross-fertilisation by visiting moths.

Lippstadt HERMANN MÜLLER

JOSEPH WINLOCK

THE following details concerning the late Prof. Winlock, whose death we announced last week, we take from the New York *Nation*:—

Prof. Joseph Winlock, Director of the Observatory of Harvard College, died suddenly after a brief illness last Friday morning, June 11, at the age of forty-nine. One of the foremost of American astronomers, whose honourable career in science began thirty years ago, who has filled with great credit several important positions of scientific labour and trust, is thus cut off in the midst of a life whose usefulness cannot be estimated by ordinary standards. Well known and highly estimated by all active collaborators in astronomy both at home and abroad, he was never so well known to others or to the public as his important services deserved. This was chiefly on account of a modest shrinking from any candidacy for honours, amounting almost to an aversion from them, and an indifference to an uncritical or merely popular reputation. Immediately upon graduating from Shelby College, Kentucky, in 1845, he was appointed Professor of Mathematics and Astronomy in that College, where he remained until 1852, when he removed to Cambridge, Mass., and took part in the computations of the *American Ephemeris and Nautical Almanac*, then under the superintendence of Admiral C. H. Davis. In 1857 he was appointed Professor of Mathematics of the United States Navy, and in that capacity served in succession as Assistant at the Naval Observatory at Washington, as Superintendent of the *Nautical Almanac*, and as Director of the Mathematical Department of the Naval Academy at Annapolis, Md. On the breaking out of the war, in 1861, he was a second time made Superintendent of the *Nautical Almanac*. His next service to astronomy was in the position of Director of the Observatory at Harvard College, and Phillips Professor of Astronomy, to which he was appointed in 1865—a position already made highly honourable by the labours of his predecessors, the distinguished astronomers, Professors W. C. Bond and G. P. Bond. He has also served at the same time as Professor of Geodesy in the Mining School of Harvard College. Only a few months ago, Mr. Bristow appointed him the chairman of the Congressional Commission for

Investigating the Causes of Steam-Boiler Explosions. These many appointments to places of responsibility are evidences of the rare sagacity, skill, sound judgment, and integrity of character which were qualities conspicuous to all who knew him well or dealt with him in his various duties. Upon taking charge of the Cambridge Observatory, he proceeded with energy to complete its equipment, adding to its already famous resources a meridian circle, constructed in accordance with his designs by Throughton and Simms of London—an instrument whose performance has been pronounced by competent judges the best of its kind in the world. The distinguished astronomer, Adams, of Cambridge, England, subsequently ordered an instrument from the same makers to be constructed on the same model. Prof. Winlock also secured for this Observatory a very perfect astronomical clock, made by Frodsham of London, from which, through contrivances of his own, true time is telegraphed to neighbouring cities. He also set the famous equatorial instrument of the Observatory upon a new career of usefulness and glory in astronomical spectroscopy. In 1870 he put into regular working efficiency a mode of observing the sun—namely, by a single lens, a heliostat, and photograph—which he independently conceived, and was the first to utilise as a form of systematic observatory work. French astronomers have lately been contending with one another about priority in the conception of this method of observation, which was so important a part of the equipment for observing the transit of Venus last December furnished to American expeditions; but in all that really constitutes effective originality, the honour of this invention undoubtedly belongs to Prof. Winlock. He was, however, almost entirely indifferent, in the singleness of his devotion to his favourite science, to popular fame, or even to contemporary recognition. Besides his observatory work, he was engaged on two occasions in the direction of expeditions to observe solar eclipses—namely, that to Kentucky in August 1869, and that to Spain in December 1870. Though ingenious as an inventor, his judiciousness was so much more prominent a quality that his originality is shown rather in a thoroughness and detailed efficiency of contrivance than in the more brilliant qualities that distinguish the more famous inventors. Very numerous little but very effective improvements in astronomical methods distinguish the astronomical art of the present day; and in these Prof. Winlock's originality was considerable. Among his published works, besides the "Annals of the Observatory" under his directorship, are a set of tables of the planet Mercury (arranged with characteristic neatness and ingenuity); brief papers in astronomical journals and in the *Proceedings of the American Academy of Arts and Sciences*. He was a native of Kentucky, and the grandson of General Joseph Winlock, who entered the American army at the beginning of the Revolutionary War, and also served in the war of 1812, and was a member of the convention which drew up the constitution of the State of Kentucky.

INDIA MUSEUM, SOUTH KENSINGTON

THE India Museum, which was opened in South Kensington last month, was founded by the Court of Directors of the Honourable East India Company in 1798. In 1860 it was removed from Leadenhall Street to Fyfe House, and in 1869 to the India Office. The galleries of the Exhibition Building, in which it is now temporarily lodged, have been leased from H.M. Commissioners for the Exhibition of 1851 for three years. The lower gallery is devoted to Raw Products, and the upper gallery to Manufactures. The present arrangement of the India Museum Collections is to a large extent only temporary, and fulfils mainly the purpose of bringing them into view preparatory to their final classification. The preparation of Descriptive Catalogues will go hand in hand with the completion of the different groups.

A handy little penny Guide has in the meantime been officially issued, which will be found of considerable service in enabling the visitor to make a systematic inspection of the large collections which have been for so long stowed away in various cellars and ware-rooms in the topmost story of the New India Office. Now that this Museum has been brought "to the light of common day," and that the public has a chance of estimating the value of its treasures, we are sure that when the lease of the Exhibition rooms expires, permanent accommodation will be allotted to it, we hope in connection with an India Institute so ably advocated by the Director of the Museum, Dr. Forbes Watson. On four days of the week the charge for admission is only one penny, and sixpence on the other two days. We purpose at present to give some account of the Botanical and Zoological Collections in the Museum.

Room No. 1 is devoted to the commercial products of the vegetable kingdom, with the mechanical appliances associated with their cultivation, collection, or preparation, and is under the superintendence of Dr. M. C. Cooke. A complete collection of these products is exhibited in small tin cases with glass fronts, which are arranged in metal frames, and suffice to give a general view of the productions of the country. Supplemental to this the principal trade articles receive special illustration in a more extended manner in central cases. As this is a new feature in the arrangement of this section, it will take some time before it can be fully and properly developed. What has been done with cotton will in part illustrate what is intended with other products. In this instance the cotton is shown from all parts of India, at first in the boll, then in the seed; afterwards cleaned, together with the seed and oil therefrom, with the waste obtained in the processes of cleaning and spinning and its economic applications. The processes of spinning are next illustrated, with the resultant twists and yarns. These are succeeded by grey and bleached cloth, printing blocks, samples of dyed and printed fabrics, and coloured yarns. Underneath these cases are arranged the agricultural implements employed in the cultivation of cotton, churkas and rollers for cleaning it from the seed, models of spinning wheels and other appliances illustrating the manipulation of the cotton fibre. Above the cases are displayed drawings of the varieties of cotton plants, and of the natives at work at the different processes through which the cotton passes from the ploughing of the soil to the complete woven fabric. By this mode the whole history of the progress of cotton from first to last is exhibited at one view, or at least as much of it as could be compressed within available space. Hitherto, although agriculture, and especially its food products, has been fully illustrated, forestry has not had by any means the share which its importance demands. It is contemplated therefore to expand this new division considerably by the addition of collections of the timbers of the three presidencies and of native states, each by itself, so as to show the character of the forests in each division, accompanied by maps and drawings or photographs of the trees. The products of the forests, other than timber, will be shown collectively for the whole of India, accompanied by such diagrams, drawings, and statistical tables as may be necessary; and the fungoid pests and enemies of arboriculture will also be illustrated. Already this illustrative mode of exhibition has commenced, but will evidently proceed slowly, as diagrams, drawings, and tables will have to be constructed, and probably some of the illustrations must be obtained direct from India.

It may be remarked that Cinchona Bark from the Neilgherry plantations, as well as from Kangra, has the honour of a case to itself, and it is hoped that soon another important drug recently introduced—Ipecacuanha

—will be represented by samples grown in India. The economic plants introduced into India must necessarily form an important feature in its trade museum. Amongst trees *Eucalypti*, the baobab, cork oak, mahogany, have not as yet produced marketable results; but tea, cinchona, senna, nutmegs, pepper, cinnamon, cloves, barley, tapioca, the Maranta arrowroot, Orleans and Egyptian cotton, with their hybrids, Carolina rice, &c., are a few of the instances in which the successfully introduced plants have added, or promise to add, considerably to the exports of India. In the development of the natural resources of so vast a region undoubtedly much remains to be accomplished. Passing through this room, a great number of such unknown, undeveloped, or unappreciated objects will not fail to impress themselves upon the attentive observer. Surely with such vast forests, and a system of conservation so steadily pursued, more ornamental and furniture woods are destined to be exported than yet find their way to the coast; and there are at least sound timbers little inferior to teak, such as *Hopea odorata* is said to be, which require only to be more widely known to be more generally appreciated. In resinous products the European markets are as yet but little indebted to the forests of India, but the copals here shown from *Hopea odorata* and *Hopea micrantha* give considerable promise. The wood oils produced by several species of *Dipterocarpus*, and the Burmese lacquer derived from *Melanorrhœa usitatissima*, might be obtained in large quantities, and yet hitherto no practical application for them in this country has been discovered. The latter is employed to a very great extent in Burmah for lacquering furniture and small wares, but it is unsuited for the English process.

Amongst the objects in this room of interest to the botanist rather than to the general public may be cited the Tabashir, a siliceous secretion from the joints of the bamboo; the curious horn-shaped galls called Kakrasinghee, produced on a species of *Rhus*; manna obtained from *Tamarix indica* in the North-west Provinces, and a kind of manna named Shirkhist from the Punjâb, attributed to the *Fraxinus floribunda*; the resin somewhat resembling Elemi, derived from *Boswellia Frereana*, which the late Daniel Hanbury considered one of the ancient kinds of Elemi, but which is disputed on good grounds by Dr. Birdwood; narcotic Indian hemp in different forms, including the Churrus or hemp resin, and various confections into which it enters; the clearing nuts which are employed by natives in clearing water, and are the seeds of a species of *Strychnos*. To which may be added the paper-like bark of *Betula bhojpatra*, used in Northern India as a wrapper for cigars; the bark of one of the species of *Daphne*, from which the renowned Nepal paper is made, and the singular natural sacks made of the bark of *Antiaris saccidora*.

The models of native implements associated with the respective "products," drawings and photographs of the mode of using them, the copious illustrations of plants from whence useful substances are derived, and especially the series of photographs of forest trees, are calculated to increase the public interest in this collection, and add to its usefulness, although these features are not yet developed to the extent or in the systematic manner which they are intended to assume.

Rooms Nos. 4 and 5 contain the zoological collections, under the superintendence of the assistant curator, Mr. F. Moore. In it are comprised the various collections of Mammals, Birds, Insects, &c., contributed by officers of the old East India Company, whose names have been distinguished by their labours in this branch of natural history, of whom may be mentioned Buchanan, Cautley, Finlayson, Hodgson, Horsfield, M'Clelland, Raffles, Roxburgh, Russell, Wallich, &c.

Commencing with the Mammals, in Room No. 5, the various tribes have been so arranged in the several cases that the visitor at a glance may see the principal species in each group. From want of space, however, many of the larger species are at present precluded from being exhibited, and it is proposed to substitute photographs and other illustrations of them.

Following in order come the Birds, which have also been arranged in a similar manner, each group or tribe being represented by prominent and characteristic species.

In this room are also deposited the cabinets of Insects, several groups of which are provisionally exhibited in the window recesses, as well as an unique collection of Indian forest insect pests.

The tribes of Reptiles and Fish are shown in Room No. 4, and, though at present but few species are represented, this section will shortly be enriched by the extensive and valuable collections formed by the Inspector-General of Indian Fisheries.

Supplemental to these groups, which are arranged in a scientific series, these rooms contain an important collection of economic animal products, including an unique series of the silk-producing insects, lac, honey-yielders, and gall-making insects of India, and their several valuable products, as well as groups of pearl-oysters, chanks, wools, plumes, horns, ivory, &c.

For a series of fossils and plaster casts from the Cautley and Falconer collections, as well as the collections of shells and Crustacea, no cases have as yet been erected for their reception.

*THE BIRDS OF GREECE**

THE third part of Mommsen's Griechische Jahreszeiten is devoted to an article upon the birds of the classical land, to our better knowledge of which Herr Mommsen's work is intended to contribute—an article which will be quite as interesting to naturalists as to the scholars for whom the periodical in question is primarily designed. The memoir is based upon the notes and observations made during his long residence in Greece and the adjoining parts of the Levant by Dr. Krüper, a naturalist well known to all students of European ornithology for his accurate and painstaking investigations of the birds of those countries, and especially for his discoveries of the breeding haunts of some of the rarer species. Dr. Krüper's notes have been further augmented in value by the co-operation of Dr. Hartlaub, of Bremen, one of the first of living ornithologists, who has contributed the references to the previous authorities upon each species, and a list of the existing memoirs relating to the same subject, besides adding many extracts from former writers to Dr. Krüper's observations.

The total number of species of birds noticed by Dr. Krüper in the present memoir is 358, on each of which notes of a more or less extended character are given. The arrangement adopted for the sake of convenience is that of Lindermayer's "Vögel Griechenlandes," published at Passau in 1860, and hitherto generally recognised as the best authority upon Grecian ornithology. Dr. Krüper's memoir must now, however, be referred to as more complete, and contains many recent additions to Lindermayer's list. We observe, however, that the work extends into limits which cannot (at any rate at present) be called Greece in its modern sense, as Dr. Krüper's recent discoveries in the neighbourhood of Smyrna of such birds as *Picus syriacus*, *Sitta kruepe*r*i*, and *Cossypha gutturalis* are introduced into it. It is, however, a matter of great convenience to ornithologists to have Dr. Krüper's notes upon the Birds of Greece and the Levant, many of which have been scattered through the pages of half a dozen periodicals, reduced into order under such excellent superintendence. Dr. Hartlaub's

* Griechische Jahreszeiten; unter Mitwerkung Sachkundiger, herausgegeben von August Mommsen. Heft iii. Schleswig, 1875.

numerous references render the volume of still greater value, and make it one that no naturalist who is interested in the Birds of Europe should omit to consult.

NOTES

ON July 5 the Sub-Wealden boring had reached the depth of 1,400 feet, and it is expected that this week it will have reached 1,500 feet. But this will have quite exhausted the funds of the Committee, and Mr. Henry Willett appeals for more subscriptions. "It cannot be too widely known," he states, "that unless 2,000 feet be reached, the solution of the problem is as far off as ever. We have met with nothing to show that Palæozoic rocks, as anticipated, may not lie at the estimated depth." We are inclined to think that Mr. Willett is too desponding in thinking that failure "seems to be imminent" from want of funds. We are sure there are many wealthy men, who, if the importance of the undertaking were properly represented to them, would come to the rescue and advance the trifling sum necessary for the completion of the experiment.

ON Saturday last, Sir George B. Airy, the Astronomer Royal, was entertained at the Mansion House on the occasion of the freedom of the City having been voted to him. A considerable number of well-known scientific and other gentlemen were present.

THE Royal Commission on Vivisection held their first regular meeting on Monday. The offices of the Commission are at 13, Delahay Street, Westminster.

IN connection with the recent volcanic eruptions in Iceland, which have caused great loss and much suffering to the inhabitants, the *Times* publishes the following abstract of a report by the Very Rev. Dean Sigurd Gunnarsson, dated Hallormsstad, in Múlasýsla, April 24, 1875:—"On Easter Monday, early in the morning, loud rumbling noises were heard to the westward, and apparently travelled towards the north-east, in the direction of the mountain ranges bounding the valley of Fljótsdalshérad to the north. Presently the sounds turned backward along the southern mountains as well. The air was heavy and jet black towards the north and north-east. About nine o'clock whitish-grey scoriaceous sand began to fall from the sky, the particles averaging the size of a grain, but in shape longer. The dark column moved on nearer and nearer, and the darkness rapidly increased, while the scoriaceous hail thickened at the same rate. A full hour before noon candles had to be lighted in the houses, and at noon the darkness was as dense as that of a windowless house; even abroad the fingers of the hand could not be distinguished at the distance of a few inches from the eye. This pitch darkness lasted for about an hour. During the dark all glass windows appeared like mirrors to those inside, reflecting the objects on which the light fell as if they had been covered outside with a coat of quicksilver. For four consecutive hours it was necessary to have lighted candles in the houses. During all that time the ashes and the sand were falling thick and fast. Lightning and claps of thunder were at the same time seen and heard in rapid succession, and the earth and everything seemed to tremble again. The air was charged with electricity to such an extent that pinnacles, and staff-pikes of iron when turned into the air, and even one's hands when held up, seemed all ablaze. But the thunder differed from ordinary claps in this, that it travelled in rapidly-repeated echoes across the skies. When the darkness wore off the fall of the ashes abated. The dark column now moved inland towards the upper valleys; but, being there met by a counter current of air, it remained at first stationary for a while, and afterwards moved slowly down country again along the valleys, so that once more the daylight was changed into dusk, which was accompanied by the fall of fine ashes. After the fall the earth was covered with a layer of ashes and scoriæ from 1½ inches to 8 inches deep; coarsest where it lay thickest, in many cases exhibiting pumice boulders twice as large as the fist. In these places the ashes fell hot as embers on the ground. At first the fall of the ashes was accompanied by a foul sulphurous stink, which, however, very soon vanished. When the ashes had any perceptible taste it was that of salt and iron. For three days after the fall still weather prevailed, and the ashes lay undisturbed on the earth. Before the fall of the ashes the land was snowless and pasture plentiful; but after it not a creature could be let out of doors, and the sheep, if they were let out, would run as if mad in all directions. On the fourth day a pretty stiff south-west gale blew the ashes away from the hillocks and mounds, except the finest part, which remained on the sward, presenting the appearance of a compact scurf. But what little good this gale might have done was undone the next day by a wind blowing from north-west."

THE *New York Tribune* publishes additional information respecting the disastrous earthquake in South America. The locality where the earthquake occurred is the great coffee district of South America. The region affected by the shocks covers five degrees of latitude, and is 500 miles wide. The shock extended in a north-east direction along the northern range of the Andes. It was felt first very perceptibly at Bogota, the capital of New Granada, thence seemed to travel north, gathering intensity as it advanced, until it reached the south-east boundary line of Magdalena, where the work of destruction began, continuing as it advanced along the eastern boundary of Magdalena, following the line of the mountain range, and destroying in part or whole the cities of Cucuta, San Antonio, El Bosario, Salazar, San Cristobal, San Cayetano, and Santiago. The first premonition of the terrible visitation occurred on the night of May 17, when a strange rumbling sound was heard beneath the ground, although no earthquake occurred. It travelled in the direction afterwards taken by the earthquake, and lasted only a few minutes. On the morning of May 18 a terrible shock occurred. It suddenly shook down the walls of houses, tumbled down churches and the principal buildings, burying the citizens of the place in the ruins. Another shock completed the work of desolation. Three more shocks followed of equal intensity, but there appears to be no evidence that there were any openings in the earth, which on similar occasions have engulfed buildings and inhabitants, at least not in Cucuta. The shocks, with lesser force, however, seem to have been felt throughout the whole region of the earthquake for two days afterwards, extending to Cartagena and the western sea-coast. To add to the horror of the calamity, the Lobotera Volcano suddenly began to shoot out lava in immense quantities, or, as a correspondent writes, "it sent out a mass of molten lava in the form of incandescent balls of fire into the city."

DETAILS concerning Mr. Giles's exploration of the country lying about 100 miles from the coast-line of the great Australian Bight have come to hand (see vol. xii. p. 135). The country he examined seems almost useless for pastoral purposes, the greater part of it being dense scrub, "heavy red sand-hills with thick mallee, mulga, acacia, Grevilles, casuaxina, hakea, and spinifex." For 200 miles the greatest suffering was endured from the want of water, the horses all dying, and the party only being saved by the camels; Mr. Giles speaks of the latter as "wonderful, awe-inspiring, and marvellous creatures." He just touched the edge of Lake Torrens, and from what he has seen he judges that there exists a vast desert of scrub of a triangular form, the base of which is at or near the western shores of the lake, and the sides running north-westerly from the southern foot, and most probably west from the northern cone to an apex at no great distance from his starting-point, Youldeh. It consists of two

deserts divided by a strip of open country about thirty miles broad; the western one Mr. Giles has named Richards' Desert, and the eastern one Ross's Desert. His starting-point was Youldeh, 135 miles N.N.W. from Fowler's Bay. At Pyleburg, sixty-four miles from this, is an extraordinary native dam, and a clay tank, with circular wall five feet high around it, the work of the aborigines. Mr. Giles is confident of being able to cross to the settled district of Western Australia.

ADVICES from New Zealand represent the last shipment of salmon ova from Glasgow to that country as having arrived in a worthless state. The total length of time during which the eggs were packed on board ship was 121 days, or only nine days longer than the period during which it has already been proved by Mr. Buckland and Mr. Youl that the development of salmon may be safely retarded by ice. A large quantity of the ice remained till the end of the voyage, so that the temperature of the ice-houses must have been kept very low throughout the voyage. In fact it is said that the *exterior* of the packing never exceeded 43° Fahr. The officers of the Otago Acclimatisation Society state that microscopic examination proved that many of the eggs were unfertilised: but this was not the case with all; and it is hardly to be supposed that so experienced a pisciculturist as Mr. Buckland, who had charge of the operations of collecting and packing the eggs, could have improperly performed so important a duty. It is more than probable that of the large number of ova sent, many were handled by incompetent assistants. But this theory will not explain the want of vitality in the impregnated eggs, especially when the conditions for their safe transit were so favourable. The cases in which they were packed are described as "sodden," so that they did not suffer from dryness. It is probable, therefore, that want of ventilation was the cause of the failure of the experiment. It will be interesting to receive more detailed information from New Zealand, as our present advices hardly enable us to judge accurately of the state of the whole consignment.

AT the time of his death Dr. J. E. Gray had compiled a list of the books, memoirs, and miscellaneous papers of which, during his lengthy life, he had been the author. This Mr. J. Saunders has completed and seen through the press, a fitting last service to his illustrious chief. The total number is 1,162.

THERE is no professional branch of practice which is so much in need of elevation as the veterinary. On this account we feel particular pleasure in noticing the commencing number of a new monthly journal, the *Veterinary Journal*, conducted by Mr. George Flemming, of the Royal Engineers, whose valuable Manual of Veterinary Science and Police, as well as his other contributions to veterinary science, make it certain that the undertaking will not be found lacking in enterprise and the outspoken criticism of existing abuses. Messrs. Baillière, Tindall, and Cox are the publishers.

THE third part of the eleventh volume of the Transactions of the Zoological Society consists of a monograph by Prof. Owen on *Cnemiornis calcitrans*, the huge extinct Lamellirostral bird of New Zealand. We omitted to mention in connection with the preceding part of the same work that the monograph on the Birds of the Philippine Islands is by Lord Walden, President of the Zoological Society.

THE subscription for the families of the unfortunate aëronauts, Sivel and Crocé-Spinelli, has reached 3,200*l*. A monument will be erected by means of a special fund. The two aëronauts will be represented sleeping, wrapped in a large mantle, and the statue will be executed in marble, life size.

A VERY valuable publication is the "Seventh Annual Report on the Noxious, Beneficial, and other Insects of the State of Missouri," made to the State Board of Agriculture by Mr. Charles V. Riley, State Entomologist. It argues considerable enlightenment on the part of the Government of Missouri that they keep a State Entomologist, though Mr. Riley complains that his work is much hindered from want of sufficient funds. The necessity for such an official in Missouri is proved by the fact that a single insect, the Chinch Bug, filches nineteen million dollars from the pockets of the farmers in a single year, and reduces by so much the wealth of the State. "Yet, though the sum demonstrably amounts to millions," Mr. Riley states, "many of our legislators and some of our journalists would laugh at me were I to ask for an appropriation of five or ten thousand dollars to be expended in experiments which might result in giving us a perfect, or at least a much better remedy for the evil than any now in our possession, and thus save the whole or the larger part of this immense annual loss." In cases, as with the Locust, the Chinch Bug, the Cotton Worm, &c., where the evils are of a national character, Mr. Riley rightly advocates the appointment of a National Commission for the express purpose of their investigation, and consisting of competent entomologists, botanists, and chemists; and we are glad to learn that preliminary steps have been taken by some of the leading scientific men in the United States to memorialise Congress to create such a Commission, the members to be chosen by the Council of the National Academy of Science, and approved by the Secretary to the Treasury. The present Report is wholly occupied with the following noxious insects:—The Colorado Potato-Beetle, the Chinch Bug, the Flat-headed Apple-tree Borer, Canker-worms, the Grape Phylloxera, and the Rocky Mountain Locust.

THE U.S. Smithsonian Institution has lately undertaken an exploration which promises very important results in the interest of American archæology. It is well known that on some of the islands off the south coast of California there have been found some extremely interesting remains of prehistoric occupation on the part of the aboriginal tribes of the country, these consisting of stone implements in great variety, soap-stone bowls, bone and shell ornaments, &c., forming a valuable collection already obtained for the National Museum. With a view of exhausting the locality and securing whatever may still remain of interest, the services of Mr. Paul Schumacher, who had previously explored the region, have been secured by the Smithsonian Institution, and he left San Francisco early in May, with four labourers, for the scene of action. The U.S. Treasury Department gave him transportation on the revenue steamer *Rush*, and the War Department supplied tents and camp equipage. It is expected that this investigation will occupy several months, and that the results will be almost as interesting in their relations to American archæology as those of Di Cesnola in Cyprus, and of Schliemann in Troy, to that of the Old World. The special object of this investigation is the furnishing of material for the grand display to be made at the Centennial by the combined efforts of the Smithsonian Institution and the Indian Bureau.

THE Eighth Annual Report of the Trustees of Cambridge, U.S., Peabody Museum of American Archæology and Ethnology contains a memoir of Jeffries Wyman, the late Curator, to whom Mr. F. W. Putnam has succeeded. The Report contains besides some account of the additions made to the Museum since last Report, which are extensive and valuable. One of the principal additions is a collection of earthen dishes and vases, a number of bone and stone implements and miscellaneous articles from mounds near New Madrid, Missouri, and several stone implements from various localities in that State, collected by Prof. G. C. Swallow. This is a very important collection, particularly rich in articles of pottery and stone of the mound-builders. The Report contains a pretty full account of these with many illustrations, especially of articles of pottery of very varied and remarkable shapes. The mounds from which

they were taken appear very ancient; soil has formed on them to the depth of three feet, and the largest trees grow on them and the connected embankments or levees. Another large collection, by Mr. F. W. Putnam, comes from fortifications, caves, and mounds in Indiana and Kentucky, and consist of implements, weapons, pottery, sandals, bark-cloth, crania, &c.

MR. F. CLOWES, B.Sc., has been appointed Natural Science Master in the recently-established Middle Class Public School at Newcastle-under-Lyne. Mr. Clowes is the author of a work on Practical Analysis, and is well known as a sound and accurate chemist.

PROF. C. F. HARTT, of Cornell, U.S., has been appointed, with Major Continho, a Brazilian, to take charge of the Geological Survey of Brazil.

IT is estimated that 10,000,000 acres of land in Algeria are covered with a spontaneous growth of the Alpha plant. The exportation of this fibre for paper-making has increased very rapidly during the past five or six years. In 1869 it amounted to 4,000 tons, in 1870 it rose to 32,000 tons, and in 1873 to 45,000 tons, while the past year's produce was expected to reach 60,000 tons. The average price at Oran is about 140 francs per ton.

A VERY fine specimen of the singular rubiaceous epiphyte *Hydnophytum formicarium* has recently been received at the Kew Museum. This specimen measures some thirteen inches through, and was accompanied by some of the ants which make their nests in the fleshy tubers of the plant. These ants were very lively when received, and prove to be the *Camponotus irritans* of Smith.

PROF. BRADLEY, of Knoxville, Tennessee, has recently published the results of his geological labours among the Southern Appalachians, and they throw much light upon the probable age of the crystalline rocks of that region. It has long been the tendency of geologists to regard the metamorphic crystalline rocks of the Atlantic coast as certainly pre-Silurian. This has, however, been called in question by the observations of Prof. Dana, which go to prove that the limestones and accompanying schists and quartzites of Western New England are *all* Silurian, and not Huronian or Laurentian. Prof. Bradley now claims the same for the region he has investigated, that is, the western portion of North Carolina, the eastern part of Tennessee, and much of Georgia and Alabama. The evidence upon which the conclusion is based is stratigraphical, and must be studied in detail to be fully understood. The time at which the uplift and metamorphism of this region took place is considered by Prof. Bradley to have been post-carboniferous, and it is probably referable to the close of the palæozoic.

A VERY interesting and important addition to the ethnological branch of the National Museum at Washington, U.S., has lately been made in the form of a large collection of objects of stone from Porto Rico. This was gathered from the ancient graves of the island during a period of many years by Mr. George Latimer, an American citizen residing in that place. The most noticeable features in the series consist of about fifty oval stone rings of much the size and shape of horse-collars, all variously carved and ornamented. There are also many statuettes, carved heads, triangular stones with faces of animals carved at either end, some pottery, and numerous axes and chisels—some of exquisite beauty, and polished to the highest degree. Many of them are of the green jade so much sought after by archæologists.

MR. ELLIOT STOCK sends us an essay by Mr. T. K. Callard, F.G.S., on "The Geological Evidences of the Antiquity of Man reconsidered;" being an attempt to show that man's antiquity is not so great as some eminent geologists make it to be, and that "man's advent was accompanied by the introduction of a vast number of fresh forms both in the vegetable and animal life, and that this took place soon after a great devastation of the former flora and fauna, which devastation was accompanied by ice and water."

THE *Electric News and Telegraphic Reporter* is the title of a new journal, edited by Mr. W. Crookes, F.R.S., to be published every Thursday. We wish it success.

THE sturgeon fisheries of Schleswig Holstein yielded 1,917 fish during 1874, of which 1,355 were caught in the Elbe, and 562 in the Eider. In 1873 the total was 2,174.

M. A. LANCASTER, of the Brussels Observatory, sends us a paper, reprinted from the *Bulletin* of the Belgian Academy, on the remarkable dryness of the months of February, March, and April of this year.

MR. ELLERY'S "Monthly Record of Results of Observations in Meteorology, Terrestrial Magnetism," &c., at Melbourne Observatory, for September and October 1874, are to hand.

THE latest additions to the Manchester Aquarium include twelve Octopus (*Octopus vulgaris*) from the Channel Islands; seven King, or Horse-Shoe Crabs (*Limulus polyphemus*) from North America; twelve Large Spider Crabs (*Maia squinado*) from Devonshire; two Lettered Terrapins (*Emys scripta*) from New Orleans; two Salt-water Terrapins (*Malachlemys concentrica*) from Mexico; one Horned Toad or Crowned Tapaxaxin (*Phrynosoma cornutum*) from Mexico; one Alligator (*Alligator mississipiensis*) three feet long.

THE additions to the Zoological Society's Gardens during the past week include two Macaque Monkeys (*Macacus cynomolgus*) from India, presented by Lord Lindsay; a Sloth Bear (*Melursus labiatus*) from India, presented by Mr. Richard A. Roberts; three American Red Foxes (*Canis fulvus*) from N. America, presented by Mr. Edward Darke; a Peregrine Falcon (*Falco peregrinus*), European, presented by Mr. H. J. Watson; a Water Viper (*Cenchris piscivorus*) from N. America, presented by Mr. J. F. Painter; a Gambian Goshawk (*Astur tibialis*) from W. Africa, purchased; three Indian Adjutants (*Leptoptilus argala*), two Pondicherry Vultures (*Vultur calvus*), seven Indian Cobras (*Naia tripudians*) from India, deposited; six Trumpeter Swans (*Cygnus buccinator*), a Common Fallow Deer (*Dama vulgaris*) born in the Gardens.

OUR BOTANICAL COLUMN

THE POTATO DISEASE.—It will be remembered by those of our readers interested in the potato disease, that Lord Cathcart offered a prize in 1873 for the best essay on the "Potato Disease and its Prevention;" and it will also be fresh in their memories that of the ninety-four essays sent in, not one was considered by the judges to deserve the prize. This circumstance, and Prof. Dyer's summary of the history of what was known of the disease, delivered before the Horticultural Society last year, gave rise to some correspondence in this and other journals. Few subjects, probably, have been so fertile a source of wild theories and speculations. Mr. Eccles Haigh, one of the competitors for Lord Cathcart's prize, now comes before the public on his own responsibility, with a theory which at least has the merit of ingenuity, and is based upon a cleverly worked out idea. But it seems to us that the writer has taken up a wholly untenable position. In a pamphlet of forty-four pages, small octavo, the writer traces the causes not only of the murrain, in which *Peronospora infestans* is so destructive, but also of the "curl," a disease very prevalent just before the appearance of the present scourge; and, to his own satisfaction, explains how these diseases are to be prevented. To be brief, gardeners are credited with having induced by their mode of cultivation the "curl," and afterwards, in getting rid of that, brought on the present far more formidable scourge. Mr. Haigh endeavours to show that during the "curl"

period the potato bore enormous crops of berries, whilst since the prevalence of the murrain it has almost ceased flowering and fruiting; and in these facts (?) lies the whole gist of the matter. The production of fruit in profusion is regarded as an exhausting process so far as the tubers are concerned, and this is so far a very philosophic assumption, inasmuch as fruit-bearing is one of two ways to ensure the propagation of the plant. But here it becomes necessary to give the author's view respecting the "Functions of Nitrogenous Matter." It is in substance that the formation of fruit draws the nitrogenous matter from the plant and tubers, and when excessive crops of fruit are borne, the tubers are left without sufficient of this vital principle to continue the existence of the plant. On the other hand, when little or no fruit is produced, the tubers are left overcharged with this nitrogenous matter, which here becomes a source of decomposition, in proof whereof we are gravely told that the decay of manure is due to the presence of nitrogenous matter. It has long been admitted that excessive luxuriance predisposes in favour of disease; but this assumed presence of nitrogenous matter in the wrong place will hardly be accepted as an adequate explanation of the phenomena presented by the curl and the murrain. It is assumed that the potato left off bearing berries just about the time of the appearance of the murrain, and this we are told was brought about by the use of artificial manures containing a large percentage of nitrogenous matter. The "curl" was cured or rather prevented by using sets (tubers) from plants which had not been allowed to ripen seed. We have not space to examine the writer's arguments in support of this theory, but we may give his remedy.

"Having so fully set forth the natural habit of the plant, and so copiously elucidated the principles on which my theory of the disease is founded, the means of its prevention all but suggest themselves. They require compliance with but two simple forms: regenerate through the seed two or three times, and abstain as nearly as practicable, not only from nitrogenous artificial manures, such as guano, sulphate of ammonia, rape-cake, nitrate of soda, but also from strong farmyard manure."

We do not intend to attempt to refute the author in detail here, as it would occupy too much space; but we may observe that the condition of practical experience imposed upon the competitors for the Cathcart prize, of which our author complains because it disqualified him, was the wisest provision in the whole business. It is just this want of practical experience and personal knowledge that has led him astray in regard to the berry-producing power of varieties now cultivated, of the description of manure usually employed, &c. Why all varieties of the potato in all parts of the kingdom should have become just so much overcharged with nitrogenous matter at exactly the same time as to take the disease is rather puzzling. Does the writer not know that the Vine Mildew, *Oidium Tuckeri*, has been successfully combated?

Since the preceding lines were written, the report of a new (?) disease having attacked the potato-crop has caused some consternation and alarm. First we hear that it has destroyed the entire crop of American varieties in the trial gardens of the Horticultural Society at Chiswick; then the appearance of the same disease is observed in Northumberland, but here again only American varieties are affected, and a vain hope is indulged in that it may soon be stamped out. The following week, however, the horticultural journals begin to team with letters from the most distant parts, and the unwelcome truth that all varieties are alike attacked, or liable to be attacked, is forced upon us. True, we read of certain varieties being diseased, whilst others remain healthy in the same garden, but we fear there is no ground for believing that it is restricted to any particular varieties, whether of English or American origin. The Rev. M. J. Berkeley is investigating the nature of the disease, which he regards with considerable anxiety. It appears to be caused by, or perhaps succeeded by, a fungus growth. At all events a fungus is present; but we must await a thorough microscopical examination for more precise information. Mr. Shirley Hibberd, in a letter to the editor of the *Times*, takes a more hopeful view of the matter than we can; and his description of the nature and spread of the disease is not borne out by the reports from other quarters. His statement that the new disease begins in the "set" and progresses upwards, is in direct contradiction to the experience of others. In the *Gardener's Chronicle* it is affirmed that the sets of affected plants were cut in two, and in no case was there the slightest evidence of disease in the tuber causing immature and diseased haulm. Possibly, however, it may manifest itself in different forms.

SCIENTIFIC SERIALS

THE *Journal of the Chemical Society*, April and May.—The April number contains the following papers:—Researches on the paraffins existing in Pennsylvanian petroleum, by Thos. M. Morgan. This paper is followed by some remarks on the same subject by Prof. C. Schorlemmer.—On Groves' method of preparing chlorides, by the same.—A note on aricine, by David Howard.—On the precipitation of metals by zinc, by J. L. Davies. The author failed to precipitate to any large extent many of the metals which, according to some metallurgical books, are precipitated by zinc from acid solutions. Copper and the other well-known metals reduced by zinc precipitate well enough, but nickel, cobalt, iron, &c., do not. If, however, ammonia was added to their solutions the precipitating power of the zinc was rendered as efficient as under ordinary circumstances it is with copper, &c. The zinc was used in the shape of filings, and the author remarks that the metals precipitated by it under the above circumstances present a beautiful metallic appearance, and are in a weighable form.—On the action of the organic acids and their anhydrides on the natural alkaloids (Part III.), by G. H. Beckett and C. R. Alder Wright. The authors in this paper treat first of the action of acetic anhydride on the polymerides of codeine and morphine (dicodeine, tetracodeine, and tetramorphine being considered, further also the action of ethyl iodide on tetracodeine and octacetyl-tetracodeine); they then speak of isomeric diacetyl morphines, and of the action of ethyl iodide on acetylated morphine, codeine derivatives, and analogous products. The compounds treated of in the latter division are diacetyl-codeine ethiodide, tetracetyl-morphine ethiodide, α-, β-, and γ-diacetyl-morphine ethiodide, dibutyryl-codeine ethiodide, tetrabutyryl-morphine ethiodide, dibutyryl-morphine ethiodide, dibenzoyl-codeine ethiodide, tetrabenzoyl-morphine ethiodide, and α diacetyl-dibenzoyl-morphine ethiodide. Finally, there is an account of the action of ethylate of sodium on acetylated codeine and morphine.—The *Journal*, as usual, contains numerous abstracts from other serials.—The May number contains the following papers:—Further researches on bilirubin and its compounds, by Dr. J. L. W. Thudichum. This is a most elaborate paper, and we must refrain from entering on its details, confining ourselves to a mere outline of its contents. First, the author gives an account of the behaviour of bilirubin with the halogens, and in turn speaks of mono- and dibromo-bilirubin, the tri- and tetrachloro-bilirubin (with iodine there is no reaction at 80° to 100°). Then Dr. Thudichum proceeds to consider the operations made by chemists on bilirubin, prior to his own. He then describes some experiments bearing upon the alleged transformation of bilirubin into the colouring matter of urine, and treats of Maly's hydrobilirubin, urochrome spectra, and the spectra of the chemolytic products of bilirubin. We then have an account of experiments made with Jaffé's product, with which Maly compared his biliary product more particularly. Jaffé's product was obtained from febrile persons, and Dr. Thudichum points out that a source of error must here be eliminated, namely, the abnormal product urerythrin. He gives the spectrum and a new reaction of this compound; finally, there is a note on Jaffé's urobilin. The paper ends with a summary of conclusions *against* the alleged metamorphosis, and with some remarks on the author's theory of bilirubin and bilirubates, and on Städeler's hypothesis regarding the same.—On calcic hypochlorite from bleaching powder, by Charles T. Kingzett. This treatise turns on the chemical constitution of bleaching powder, on which subject the opinions of eminent chemists are at variance. The author describes four experiments which he made with a view to bring light into the matter, but he was not completely successful. Although his experiments may be regarded as a perfect proof of the body being in mass hypochlorite of calcium, yet he is nevertheless reluctant in being too positive on the subject, and recommends further investigation.—On a simple method of assaying iron, by Walter Noel Hartley. The principles on which this method depends are (1) The abolition of weights by exactly balancing a quantity of the ore to be examined against pure iron wire. (2) The reduction of inaccuracies in weighing by making the solutions of the iron and the ore up to the same volume, and taking a fraction (about $\frac{1}{30}$) of the liquid for experiment, whereby the error of the balance is diminished $\frac{1}{30}$. (3) The reduction of all other experimental errors to a minimum by putting comparable quantities of both ore and pure iron under precisely the same conditions. There is the usual number of abstracts in this part.

THE *Geographical Magazine*, July.—This is a particularly interesting number of this magazine. The first article is an abstract of the narrative of Captain the Hon. G. C. Napier, who has recently returned to India after an adventurous tour in Northern Persia. An article on "Recent Russian Explorations in Western Mongolia," accompanied by a map, gives some account of (1) Sosnovski's and Miroshnichenko's explorations on the Upper Irtysh in 1872–73; (2) Matusovski's journey into the Ektag-Altai in 1873; (3) A Russian caravan journey to Kobdo, Uliassutai, and Baikul in 1872. In an article on Paraguay the leading features of the history of that country are traced. In "A Trip up the Congo or Zaire" river, Selim Agha gives an interesting account of his journey from Fernando Po to that river in company with Capt. Burton; the latter prefaces the narrative with a few words of personal notice of his old factotum and companion. To those whose interest in Zanzibar has been awakened by the present visit of its sovereign to this country, the account of the dominions of the Seyyid Burghash, along with the good map which accompanies it, will be welcomed. The usual reviews and reports fill up the number.

Journal of Proceedings of the Winchester and Hampshire Scientific and Literary Society, vol. i. part iv., 1874.—We are glad to see from the president's address that this Society is doing much real work, and especially that it is devoting itself with considerable zest and good results to field-work. The Society includes in its programme a wide variety of subjects, and its Journal contains good papers in various departments of science. The president, the Rev. C. Collier, after reviewing the Society's work for the year, gives an interesting address on the archæology of Winchester and its neighbourhood. Other papers in the part are "Selections from the Sanskrit Poets," by Mr. W. Waterfield; "Sarsens, greywethers, or Druid Stones," by Mr. Joseph Stevens; "Two-winged Plagues," a paper on Œstrids, Tabanids, and Hippoboscids, by the Rev. W. W. Spicer; "The Chalk Formation," by Mr. C. Griffith; and "A Gossip about Mites," by the Rev. W. W. Spicer.

Zeitschrift der Oesterreichischen Gesellschaft für Meteorologie, May 1.—This number contains an account of Mr. Colding's work on the behaviour and relations of atmospheric currents, consisting mainly of mathematical reasoning based upon a study of the movements of water, which he considers analogous to those of air. With regard to hurricanes, he observes that just as in a water eddy the velocity of rotation increases from the circumference towards the centre, until at the inner surface it becomes imaginary, so the velocity of the wind increases from the circumference of a revolving storm towards the centre, but at a certain distance from the centre, the boundary of the calm space, falls suddenly to stillness. He believes the following formula, which applies to water, to be good for air also, both being bounded by a resisting medium. Let water circulate in a cylinder, where H = depth of current at the circumference, V = velocity of current at the surface; then at a depth x below the surface:

$$v = V\left(1 - 0{\cdot}433\left(\frac{x}{H}\right)^{\frac{3}{2}}\right)$$

when the resistance at the base is equal to that which would be exercised by a substratum of water. If water flows in at one point in a vessel containing water, and flows out at another point, and the inflowing and outflowing quantities are equal, the surface remains at a constant level. Let the supply be in the middle and the outflow round the circumference, the water will descend towards the circumference. If the contained water be rotatory, its condition will be similar when a constant stream flows in; there will be an increase of pressure at all points, and the water will attain a higher level, descending in the directions of its escape. A whirlwind can withstand pressure from without only when the rotation has a certain velocity, and although a considerable quantity of air must flow to the whirlwind along the surface of the earth, on the other hand a permanent current must flow outwards in the direction of the surface level. In moving over the surface of the earth it encounters many obstacles, which reduce the velocity of rotation, so that an inrush of the air at higher pressure takes place, and immediately the condensed air in the lower strata forces outwards a quantity of air at the top proportionate to that which streams towards the centre below. This action of course diminishes the fury and increases the diameter of a hurricane, and exhibits the twisting motion so often observed in small whirlwinds and waterspouts. The rest of the article will be given in the next number of the *Zeitschrift*.

Der Naturforscher, May 1875.—From this part we notice the following papers:—On the atomicity of nitrogen, by Victor Meyer and M. Lecco. These gentlemen arrive at the conclusion that nitrogen is not a triad, as thought by some chemists, but a pentad.—On the process of fertilisation with fungi (Basidiomycetes) by Van Tieghem.—On the evaporation of moisture through the human skin, by Fried. Erismann.—On the cause of luminosity or non-luminosity of carboniferous flames, by F. Wibel.—On the artificial imitation of nâtive polar-magnetic platinum, by Daubrée.—On the tenor of nitrogen in soil-acid, by E. Simon.—On the behaviour of some solutions in polarised light, by O. Hesse.—On the marine flora existing at Spitzbergen during winter, by Herr Kjellman.—On the temperatures in the southern and northern Atlantic Ocean, by Herr von Schleinitz.—On melting points, by Herr Müller.—On the dependence of the action of emulsine upon physical conditions, by Herren E. Marckurst and G. Hüfner.—On hardened glass, by Herr Bauer.—On the so-called "Riesenkessel" (gigantic kettles) near Christiania and their origin, by Herren Brögger and Reusch.—On the immunity of *Gymnotus electricus* against its own electric shock, by Herr J. Steiner.—On the influence of light on the weight of animals, by Dr. Fubini.—On the dependence of the specific heat of carbon, boron, and silicon upon temperature, by Friedrich Weber.—On the action of the central organs of the nerves, by Herr Frensberg.—On the spectrum of Encke's comet, by Herr von Konkoly.—On the action of the electric current on fused amalgama and alloys, by Eugen Obach.

Monthly Notices of Papers and Proceedings of the Royal Society of Tasmania for 1873.—This has only just come to hand, and the subject matter of some of the papers has lost in interest, inasmuch as some of the phenomena discussed—the Transit of Venus, for instance—have since taken place. Mr. F. Abbot's paper on the Transit of Venus, with special reference to the importance of determining the true distance of the sun in connection with meteorology, is a most interesting contribution. Speaking of the effects of conjunctions, he alludes to the fearful storm which took place Nov. 27, 1703, when five of the planets were in conjunction. The storm swept over the continent of Europe, causing an immense amount of damage. It was on that day the whole structure of the first Eddystone Lighthouse, together with its architect, Winstanley, and other inmates, was blown into the ocean.—The principal other contributions are on the Mersey coal-measures, by T. Stephens, M.A.; on the Tertiary Beds in and around Launceston, by R. M. Johnston; Contributions to the Phytography of Tasmania, by Baron F. Mueller; and Law of Weather and Storms, by the Right Rev. Bishop Bromby.

Reale Istituto Lombardo.—Rendiconti: vol. viii., fasc. x. and xi.—These parts contain the following papers:—On scientific association, by Prof. G. Sangali.—On the "Jaborandus," by Prof. S. Garovaglio.—On the importance of the study of meteorology to agriculturists, by Prof. Gaetano Cantoni.—On the reasons why sulphur destroys the *Oidio* (a cryptogamic parasite) of the vine, and on the emission of free hydrogen from plants, by Prof. E. Pollacci.—On two questions relating to chimneys, by Prof. R. Ferrini.—On hydrostatic pressure in relation to the molecular motion of gravitation, by Dr. G. Grassi.—The remaining papers in this part relate to political and moral sciences.

THE *Journal de Physique Théorique et Appliquée*, May 1875, contains the following original papers:—Researches on the modifications which light undergoes in consequence of the motion of the luminous source and of that of the observer, by M. Mascart.—On the currents of mechanical origin, by E. Bouty.—On the combustion of explosive mixtures, by M. Neyreneuf.—On the apparatus used for the explanation of the laws and formula of elementary optics, by C. M. Gariel.—On the determination of the electric capacity of bodies and of their condensing power by means of Thomson's electrometer, by M. A. Turquen.—A note by M. C. Daguenet, on the electric light in rarefied gases.

Verhandlungen des Vereins für Naturwissenschaftliche Unterhaltung zu Hamburg, 1871–74.—This is the Vereins' first publication, and contains an account of the formation and of the first year's doings of the Society, together with a copy of the laws and regulations, and a list of members. Further on we have several well-written articles, viz.:—On the preparation of caterpillars for collections, by G. J. Wittmack.—On some attempts at silk-culture with *Bombyx mori*, by Georg Semper.—Researches

on the effects of trichinæ on white rats, by C. Rodig.—On a method of preparing slugs for dry keeping in collections, by F. Hübner.—Geological recollections of a few weeks at Weymouth, by Dr. Filby.—Some remarks on *Cypraeæ*, by Dr. Aug. Sutor. On the homoptera of Schleswig, by Dr. H. Benthln.—Finally, there are a number of papers relating to the fauna of the Lower Elbe, some of which are highly interesting.

THE March number of the *Bulletin de la Société d'Acclimatation de Paris* contains, among other papers, one by M. E. Rénard, on a new kind of bamboo, and the articles made from the canes of this species of plant. This particular variety is square, and is found in the Chinese provinces of Honan and Se-tchuen.—M. le Comte Pouget, in a note on the Kagou, describes a new bird known by that name in New Caledonia, of which it is a native, and called *Rhynochetos jubatus* by ornithologists. The bird is entirely insectivorous, feeding on almost every kind of insects and worms, and appears to thrive in the climate of France.—M. Gildas, a priest in the monastery of Nôtre Dame de la Trappe des Trois Fontaines, near Rome, gives a description of the growth of Eucalyptus trees in the Roman Campagna; the salubrity of the locality has, partly in consequence of sanitary works, and partly probably in consequence of the effect of these trees, been greatly increased of late years.—The Colorado potato beetle (*Doryphora decemlineata*) is being made the object of special research by members of the Society. M. Maurice Girard states that as this insect does not exist always in close contact with the plant on which it lives, it will probably suffer from the change of climate to which it is subjected by transportation from America to Europe, and will consequently die off. Had it been, like the Phylloxera, an insect living always closely fixed to the tree on which it preys, there would have been greater danger of its permanent introduction into other countries.

SOCIETIES AND ACADEMIES

LONDON

Anthropological Institute, June 22.—Col. A. Lane-Fox, president, in the chair.—A paper by Mr. Herbert Spencer was read on the comparative psychology of man. The author commenced by showing the necessity for division of labour in a systematic study of psychology, and proceeded to map out the subject into divisions and subdivisions, and to indicate the manner in which its various branches might be investigated. The main divisions were—mental mass and complexity, the rate of development, plasticity, variability, impulsiveness, difference of sex, the sexual sentiment, imitation, quality of thought, peculiar aptitudes, with their many subdivisions. Mental effects of mixture, and the inquiry how far the conquest of race by race has been instrumental in advancing civilisation, would also come within the scope of comparative psychology.—Mr. John Forrest read an account of the natives of Central and Western Australia, whom he had observed during two journeys he had made across the country from Western to South Australia. Among their customs might be mentioned that of tattooing on the shoulders, back, and breast, and the practice of boring noses, which is raised to the importance of a ceremony, when hundreds of individuals gather together for that object. Circumcision he found to be universal. The use of the boomerang was described, and the exaggerated statements concerning the manipulation of the weapon were corrected. Cannibalism was common among the natives of the interior. Many other descriptive details of their faith, manners, and customs were given.—A paper by Capt. John A. Lawson was read on the Papuans of New Guinea. The only part of the coast that the author examined was Houltree, and there, as in the interior, he met with a race of people dissimilar to those described by other travellers who have visited various parts of the coast. There was a marked diversity in stature; in the south of the island the people were shorter than those inhabiting the north. They were possessed of enormous muscular power, and showed a large thoracic development. Their complexion was a dark tawny, but not black, and their features were of Negroid type.

Royal Horticultural Society, June 2.—Scientific Committee.—J. D. Hooker, M.D., C.B., P.R.S., in the chair.—Prof. Thiselton Dyer made some further remarks on *Tetranychus Taxi*, A. Murr., which he thought did not attack the ordinary buds of the Yew, but, as far as he had observed, those containing the female flowers. The acarus appeared to feed on the nucleus of the ovule and the adjoining scales, the external scales became brown and withered.—The Rev. M. J. Berkeley showed specimens of *Hypoxylon octraceum*, which was figured by Bulliard, tab. 444, fig. 3. It had been referred by Fries to *Lophium mytilinum*, but was really, as Sowerby was aware, the cocoon of a midge. Mr. Berkeley had met with similar cocoons belonging to other species, and Prof. Westwood was understood to be preparing descriptions of all three.—Prof. Thiselton Dyer exhibited specimens of the capsules of *Hibiscus Rosa-sinensis*, which, though the plant was so common in gardens, were quite undescribed. According to Dr. Cleghorn, it rarely if ever fruited in India. In Barbados, on the other hand, it fruited abundantly in the garden of General Munro.—Mr. Andrew Murray read a paper on the packing of living plants for transport.—Prof. Thiselton Dyer called attention to Willkomm's "Die mikroscopischen Feinde des Waldes," in which the Larch-canker was shown to be due to the attacks of the so-called "*Corticium amorphum*," since described by Hartig as *Peziza Willkommii*.

General Meeting.—W. Burnley Hume in the chair.—The Rev. M. T. Berkeley called attention to the more interesting objects exhibited. The young shoots of apple-trees were liable to great injury from an *Oidium*, which might, however, be destroyed by the use of sulphur; specimens were exhibited.

June 16.—Scientific Committee.—A. Murray, F.L.S., in the chair.—A letter was read from the Hon. Secretary of the Wiltshire Horticultural Society relating to some diseased potatoes, upon which Mr. Berkeley remarked that he had recently found the American varieties at Chiswick, especially the Early Rose, dreadfully affected with disease, communicated from the tuber to the haulm. Mr. Berkeley had hitherto been only able to make a superficial examination, but he suggested that possibly the disease in question was analogous to the "curl," a disease well known many years ago, but since then not noticed. He had found in the cells of the leaf an obscure fungoid organism—a species of *Protomyces*.—Mr. Bateman exhibited a package of the Paraguay tea, *Ilex paraguayensis*, together with the gourd and strainer used by the natives in the preparation of this tea, as figured in Hooker's *Journal of Botany* many years since.—Mr. W. G. Smith exhibited a drawing of the mould (*Ascomyces deformans*) which is associated with the Peach blister.—Dr. Masters exhibited on the part of the Rev. H. N. Ellacombe a portion of the main root of an apple nearly gnawn through by the Water Vole. Dr. Masters also showed *Cheiranthus Cheiri* var. *gynantherus*, to show that the peculiarity was reproduced from seed.—Dr. Hooker sent for exhibition the nest of a trap-door spider found in the bark of a tree at Uitenhage, Port Elizabeth, South Africa, where it was obtained by Mr. Bidwell, a member of the Legislative Assembly of Cape Town. The nest and the lid were so nearly like the bark itself that it was with difficulty the lid could be seen, and it was with some difficulty that the lid could be raised, as the insect was still within the nest. Mr. Murray suggested that the spider had taken possession of the empty cocoon of a moth (*Bombyx*), and had woven a lid to it with silk and fragments of bark.

General Meeting.—Hon. and Rev. J. T. Boscawen in the chair.—The Rev. M. J. Berkeley gave an account of the new potato disease, which he identified (as mentioned above) with that formerly known as the "curl."

PHILADELPHIA

Academy of Natural Sciences, Sept. 22, 1874.—Dr. Ruschenberger, president, in the chair.—Prof. Leidy remarked that he had found several specimens of the curious rhizopod, discovered by Cienkowski, and named by him *Clathrulina elegans*. They were found among Utricularia, but though retaining their stems, were unattached and apparently dead. One of the specimens presented a peculiar and as yet unexplained character. On one side of the latticed head the orifices were capped with little inverted hemispherical cups, from the top of which projected a funnel like the cup of the spongozoa. Prof. Leidy was pursuing his search for the living and attached Clathrulina.—Prof. Leeds made some remarks concerning a remarkable mineral found in a bank of white sand near Fayetteville, N.C. It was, in appearance, a rod of glass four feet in length and two inches in diameter, which was made up of a great number of irregular fragments. These fragments were highly polished on one side, the side apparently turned towards the hollow axis of the rod, and excessively contorted on the exterior side. They consisted almost entirely of silex, the remainder being chiefly oxide of iron. Accurate analysis showed that the percentages of the constituents in these siliceous

fragments and in the sand found in the hollow core of the rod were the same. On account of this identity in composition, and the incompetency of any other known agent to produce such a fusion of almost pure silex, it was concluded that this "rod of glass" was a result of lightning—a lightning-tube, or fulgurite, as such products have been called.—Mr. Thomas Meehan referred to a former communication in which he exhibited specimens of *Euphorbia cordata*, or *E. humistrata*, collected by him in the Rocky Mountains, and which, normally procumbent, had assumed an erect habit on being attacked by a fungulus, *Æcidium euphorbiæ hypericifoliæ.* He now found that the common trailing Euphorbia of our section, *E. maculata*, when attacked by the same fungulus, assumed the same erect habit. With change of habit of growth there was a whole change in specific character in the direction of *E. hypericifolia.*

Sept. 29.—Dr. Ruschenberger, president, in the chair.—On favourable report of the committee to which it was referred, the following paper was ordered to be printed:—"Notes on the Santa Fé Marls, and some of the contained Vertebrate Fossils," by E. D. Cope.

Oct.—Mr. Thomas Meehan introduced a specimen in which plants of *Triticum* and *Bromus* were blended. This Dr. J. G. Hunt proved to have been a "cheat;" neither did he think the workman had been expert in his manipulation.—Mr. Redfield drew attention to the growth, near Delaware River, of *Polygonum orientale* and *Cleome pungens*, which Prof. Leidy traced to ballast deposited there. The lastnamed author then drew attention to some new species of *Difflugia.* —Mr. Meehan announced the discovery of *Abies concolor* in Glen Eyrie, Colorado, by Dr. Engelmann; and Prof. Leidy drew attention to the devastation of the oaks of New Jersey, by the *Dryocampa senatoria.*

Nov.—Mr. A. R. Grote presented a paper on a new species of *Nocteridæ*, describing as new genera and species *Acronycta exilis*, *A. paupercula*, *Eutolype*, *Himella*, &c.; and Prof. Cope described some ruins of villages of extinct races near Nacimiento, N.M.—Prof. Leidy, besides referring to *Titanotherium*, drew attention to several Protozoa which he was studying, including species of *Clathrulina elegans*, *Amœba viridis*, &c.—Prof. P. Frazer, jun., described the geology of certain lands in Ritchie and Tyler Counties, W.V.; and Dr. Elliott Coues read a synopsis of the *Muridæ* of North America, dividing the Murinæ into the genera *Mus*, *Neotoma*, *Sigmodon*, *Hesperomys* (Waterhouse, emend.), *Ochetodon* (n.g.); and the Arvicolinæ into *Evolomys* (n.g.), *Arvicola*, *Synaptomys*, *Myodes*, *Cuniculus*, and *Fiber.*

Vienna

K. K. geologische Reichsanstalt, Jan. 5.—This was a festival meeting in celebration of the 25th anniversary of the foundation of this institution. No scientific papers were read. From those read at the subsequent meetings, Jan. 19, Feb. 16, March 2 and 16, we note the following:—Geological report from travellers in Persia, by Dr. E. Tietze.—On the Aralo-Caspian basin, by Dr. M. Neumayr.—On some pseudomorphous copper ores from the Ural, by E. Döll.—On well-sinking in the Vienna district, by T. Fuchs.—On Tertiary stone forma ions in Carniola, by the same.—On the formation of terra rossa, by Dr. Neumayr.—On a new occurrence of manganic peroxide in Lower Styria, by Dr. R. v. Drasche.—On the gneiss formation of the Bohemian forest, by Dr. J. Woldrich.—On the geological results of the railway diggings between Rakonitz and Beraun, by H. Wolf.—On the occurrence of antimony near Eperies, by L. Manderspach.—On the ores of Laurion in Attica, by A. Schlehan.—On some new silver ores from Joachimsthal, by J. v. Schröckinger.—On the lime of the Acropolis of Athens, by Dr. M. Neumayr.—On the environs of Predazzo and on the Monzoni mountains, by Dr. C. Doelter.—On the interior structure of the Offenbánya mining district and on that of the Boitza district, by F. Posepny.—On some petrifactions from the Kalnik mountains, by Dr. R. Hörnes.—On some slaked stone mounds in Bohemia, by Dr. J. Woldrich.

Paris

Academy of Sciences, June 28.—M. Frémy in the chair.—The president welcomed M. Janssen in the name of the Academy on his return to Paris, and M. Janssen made some remarks in reply.—The following papers were read:—On the explanation of numerous phenomena which are consequences of old age, by M. Chevreul.—On the work in course of execution at the Observatory, by M. Leverrier. Among other observations it is proposed to carry on a series with a view to constructing magnetic and meteorological charts of France.—Magnetic observations made in the Peninsula of Malacca, by M. Janssen. The observations were undertaken with a view to fixing the present position of the magnetic equator, which the author found to pass between Ligor and Singora. A meridian was found also in which the magnetic declination was 0°. This note is dated from Singapore, May 16.—On the distribution of magnetism in a thin bar of great length, by M. J. Jamin.—On the cyclone at Châlons; second examination of facts and conclusions, by M. Faye.—On the distribution of an acid among several bases in solutions, by M. Berthelot.—On the hydrocarbons produced by the distillation of the crude fatty acids in presence of superheated steam, by MM. A. Cahours and E. Demarcay. The authors found in a sample of oil from Fournier's stearine candle factory the following hydrocarbons: amyl, hexyl, and heptyl hydrides; likewise the hydrides of octyl, nonyl, decyl, undecyl, duodecyl, and cetyl.—Note on tabular electro-magnets with multiple cores, by M. T. du Moncel.—Note accompanying the presentation of the first volume of the "Analytical and Experimental Demonstration of the Mechanical Theory of Heat," by M. Hirn.—Influence of compressed air on fermentation, by M. P. Bert.—Memoir on the earth's motion of rotation, by M. E. Mathieu.—Study of electric discharges through fine metallic wires, by M. Melsens.—On the influence of magnetism on the extra current, by M. Trène.—Chemical equivalence of the alkalies in the ashes of various vegetables, by MM. Champion and H. Pellet.—On the presence of hydrogen dioxide in the sap of vegetables.—On the work of the expedition commissioned to study the project of a central sea in Algeria, by M. Roudaire.—Solar parallax deduced from the combination of the Noumea with the Saint-Paul observations, by M. C. André.—On the numerical values of the musical intervals in the vocal chromatic gamut, by M. Bidault.—New sounding flames, by M. C. Decharme.—Action of chlorine on isobutyliodhydric ether, by M. Prunier.—On the portative force of M. Jamin's magnets, by M. A. Sandoz.—New apparatus relating to respiration, by M. G. Carlet.—Of the influence of the noxious *Solanaceæ* in general, and of belladonna in particular, on Rodents and Marsupials, by M. E. Heckel.

BOOKS AND PAMPHLETS RECEIVED

American.—The Birds and Seasons of New England: Wilson Flagg (Trübner and Co.)—Annual Report of the Board of Regents of the Smithsonian Institution (Washington).—Important Physical Features exhibited in the Valley of the Minnesota River. An Essay, by G. K. Warren (Washington).—Proceedings of the American Philosophical Society.—Transactions of the Academy of Science of St. Louis. Vol. iii. No. 2.—Bulletin of the Essex Institute, 1874.—Report of the Geological Survey of Missouri, U.S., and Atlas to same

Foreign.—Notizblatt des Vereins für Erdkunde. 3te Folge, 13tes Heft (Darmstadt)—Nach den Victoriafällen des Zambesi, von Eduard Mohr. 2 vols. (Berlin, Ferdinand Hirt und Sohn).

THURSDAY, JULY 15, 1875

SCIENTIFIC WORTHIES

V.—George Gabriel Stokes

A GREAT experimental philosopher, of the age just past, is reported to have said, "Show me the scientific man who never made a mistake, and I will show you one who never made a discovery." The implied inference is all but universally correct, but now and then there occur splendid exceptions (such as are commonly said to be requisite to prove a rule), and among these there has been none more notable than the present holder of Newton's chair in Cambridge, George Gabriel Stokes, Secretary of the Royal Society.

To us, who were mere undergraduates when he was elected to the Lucasian Professorship, but who had with mysterious awe speculated on the relative merits of the men of European fame whom we expected to find competing for so high an honour, the election of a young and (to *us*) unknown candidate was a very startling phenomenon. But we were still more startled, a few months afterwards, when the new professor gave public notice that he considered it part of the duties of his office to assist any member of the University in difficulties he might encounter in his mathematical studies. Here was, we thought (in the language which Scott puts into the mouth of Richard Cœur de Lion), "a single knight, fighting against the whole *mêlée* of the tournament." But we soon discovered our mistake, and felt that the undertaking was the effect of an earnest sense of duty on the conscience of a singularly modest, but exceptionally able, and learned man. And, as our own knowledge gradually increased, and we became able to understand his numerous original investigations, we saw more and more clearly that the electors had indeed consulted the best interests of the University; and that the proffer of assistance was something whose benefits were as certain to be tangible and real as any that mere human power and knowledge could guarantee.

And so it has proved. Prof. Stokes may justly be looked upon as in a sense one of the intellectual parents of the present splendid school of Natural Philosophers whom Cambridge has nurtured—the school which numbers in its ranks Sir William Thomson and Prof. Clerk-Maxwell.

All of these, and Stokes also, undoubtedly owe much (more perhaps than they can tell) to the late William Hopkins. He was, indeed, one whose memory will ever be cherished with filial affection by all who were fortunate enough to be his pupils.

But when they were able, as it were, to walk without assistance, they all (more or less wittingly) took Stokes as a model. And the model could not but be a good one: it is all but that of Newton himself. Newton's wonderful combination of mathematical power with experimental skill, without which the Natural Philosopher is but a fragment of what he should be, lives again in his successor. Stokes has attacked many questions of the gravest order of difficulty in pure mathematics, and has carried out delicate and complex experimental researches of the highest originality, alike with splendid success. But several of his greatest triumphs have been won in fields where progress demands that these distinct and rarely associated powers be brought simultaneously into action. For there the mathematician has not merely to save the experimenter from the fruitless labour of pushing his inquiries in directions where he can be sure that (by the processes employed) nothing new is to be learned; he has also to guide him to the exact place at which new knowledge is felt to be both necessary and attainable. It is on this account that few men have ever had so small a percentage of *barren* work, whether mathematical or experimental, as Stokes.

Like that of the majority of true scientific men, his life has been comparatively uneventful. The honours he has won have been many, but they have never been allowed to disturb the patient labour in which short-sighted Britain has permitted (virtually forced) him to waste much of his energies. He was born on August 13, 1819, at Skreen, Co. Sligo, of which parish his father was rector. At the age of 13 years he was sent to Dublin, where he was educated at the school of the Rev. R. H. Wahl, D.D. In 1835 he was removed to Bristol College, of which Dr. Jerrard was principal. He entered Pembroke College, Cambridge, in 1837; graduated in 1841 as Senior Wrangler and First Smith's Prizeman; became Fellow of his College in the same year; and in 1849 was elected Lucasian Professor of Mathematics. In 1857 he vacated his fellowship by marriage, but a few years ago was reinstated under the new statutes of his college. Stokes was elected Fellow of the Royal Society in 1851, was awarded the Rumford Medal in 1852, and was elected Secretary of the Society in 1854.

A really great discoverer in mathematics or physics does not seek the readily-accorded plaudits of the ignorant masses or of the would-be learned rich. He knows the worthlessness of such verdicts (in any but a possible pecuniary sense); his joy is in the conviction that, within a very short time after their publication, his discoveries will be known to all who are really capable of comprehending them; that his experiments will be repeated, and in many cases even extended, by some of them before he has made further advance. He is a true soldier of science, and fights for her cause, not for his own hand; he joys quite as much in an advance made by another as in his own. When the army has passed on from the well-fought field, let the camp-followers deck themselves with frippery from the spoil, and talk pompously of the labours of the campaign! Them the many-headed will applaud, too often even sage rulers will lavishly reward them. The true votary of science, in this country at least, rarely meets with State encouragement and support. Mole-eyed State! Men whose undisturbed leisure would be of incalculable value, not only to the instruction but to the material progress of the nation, have to devote the greater part of their priceless intellects and time to work like common hodmen for their children's bread! It is the long-consecrated, and still common, custom of our mighty empire to harness Pegasus to the dust-cart! Ignorance alone is to blame for this, ignorance that cannot distinguish Pegasus from a jackass!

Perhaps the simile may be thought exaggerated. But what a comment on things as they are is furnished by the spectacle of genius like that of Stokes' wasted on the

drudgery of Secretary to the Commissioners for the University of Cambridge; or of a Lecturer in the School of Mines; or the exhausting labour and totally inadequate remuneration of a Secretary to the Royal Society! Men know about these things, as well as about a good many other important things, much better in Germany than we yet know them; and it will not be very long before we in our turn will be forced to know them to the full as well. Let us hope that this knowledge may come to us in a more gentle form than that of the rude and sudden lessons which have so lately been read (for something very like the same fatal blindness) alike to Austria and to France!

The magnificent Royal Society *Catalogue of Scientific Papers*, one of the greatest boons ever conferred on men of science, shows that up to 1864 Stokes had published the results of some *seventy* distinct investigations; on an average between three and four per annum. Several of these are controversial; designed not so much to establish new results as to upset false and dangerously misleading assertions. Some are improvements on the mathematical methods usually employed in the treatment of comparatively elementary portions of physics; and, especially those on the *Hydrokinetic Equations* and on *Waves*, are exceedingly valuable. These appeared in the *Cambridge and Dublin Mathematical Journal*.

Of the higher purely mathematical papers of Stokes we cannot here attempt to give even a meagre sketch. It would be hopeless to attempt to give the general reader an idea of what is meant by the "Critical Values of the Sums of Periodic Series," or even by the "Numerical Calculation of Definite Integrals and Infinite Series;" though we may simply state that under these heads are included some of the most important improvements which pure mathematics have recently received with the view of fitting them for physical applications.

In applied mathematics it is hard to make a selection, so numerous and so important are Stokes' papers. But we may mention specially the following:—

"On the Friction of Fluids in Motion, and the Equilibrium and Motion of Elastic Solids." *Camb. Phil. Trans.*, 1845.

"On the Effects of the Internal Friction of Fluids on the Motion of Pendulums." *Ibid.* 1850.

(In these papers, for the first time, it is shown how to take account of difference of pressure in different directions in the equations of motion of a viscous fluid; the suspension of globules of water in the air as a cloud is for the first time explained and the vesicular theory utterly exploded; and the notion of Navier and Poisson as to a necessary numerical relation between the rigidity and the compressibility of a solid is shown to be untenable. Each one of these is a distinct, and exceedingly great, advance in science; but they are only single gems chosen, as we happen to recollect them, from a rich treasury.)

Then we have a series of magnificent researches on the "Undulatory Theory of Light," for the most part also published in the *Cambridge Philosophical Transactions*. Of these we need mention only three:—

"On the Dynamical Theory of Diffraction." 1849.

(Here, in addition to a splendid experimental inquiry as to the position of the plane of polarisation with reference to the direction of vibration, we have an invaluable inquiry into the properties and relations of Laplace's Operator, an inquiry bearing not alone upon the Undulatory Theory, but also upon gravity, electric and magnetic attractions, and generally upon all forces whose intensity is inversely as the square of the distance.)

"On the Colours of Thick Plates." 1851.

"On the Formation of the Central Spot of Newton's Rings beyond the Critical Angle." 1848.

As another most important contribution to the undulatory theory we have his

"Report on Double Refraction." *British Association Report*, 1862.

Then we have a full investigation, in one respect carried to a third approximation, of the propagation of waves in water; a complete explanation of the extremely rapid subsidence of ripples by fluid friction, &c.

Another paper of great value is—

"On the Variation of Gravity at the Surface of the Earth." *Camb. Phil. Trans.*, 1849.

Perhaps Stokes is popularly best known by his experimental explanation of *Fluorescence*. This is contained in his paper

"On the Change of the Refrangibility of Light." *Phil. Trans.*, 1852.

There can be no doubt, as was well shown by Sir W. Thomson in his Presidential Address to the British Association at Edinburgh in 1871, that Stokes (at least as early as 1852) had fully apprehended the physical basis of *Spectrum Analysis*, and had pointed out *how* it should be applied to the detection of the constituents of the atmospheres of the sun and stars. Since 1852 Thomson has constantly given this as a part of his annual course of Natural Philosophy in the University of Glasgow; but, till 1859, under the impression that it was quite well known to scientific men. Balfour Stewart's experiments and reasoning date from 1858 only, and those of Kirchhoff from 1859.

In some of Stokes' earlier hydrokinetic papers, he for the first time laid down the essential distinction between rotational, and differentially irrotational, motion, which forms the basis of Helmholtz's magnificent investigations about vortex-motion.

Another most valuable paper (a short abstract of which, in the *Reports of the British Association for* 1857, seems to be all that has been published) completely clears up the difficulties which had been felt with regard to the very curious effects of wind upon sound, and the diffraction of waves in air. The singular fact noticed by Sir John Leslie that the intensity of a sound depends, *ceteris paribus*, to a marked extent upon the nature of the gas in which it is produced, is explained in an admirable manner by Stokes in the *Philosophical Transactions* for 1868 in a paper entitled "On the Communication of Vibration from a Vibrating Body to the surrounding Gas."

Of late years Stokes has not published so many papers as formerly: one reason at least has been already hinted to the reader. But there is another. It is quite well known that he has *in retentis* several optical and other papers of the very highest order, but cannot bear to bring them out in an incomplete or hurried form. No doubt he may occasionally hint at their contents in his lectures, but his (undergraduate) audience are likely to take them for well-known and recognised facts [as Thomson unfortunately did in the case of Spectrum Analysis], and so

they run the risk of being wholly lost—unless independently discovered. But he has not time to draw them up with the last possible improvements, nor to publish that Treatise on Light and Sound which we all so eagerly expect. Hence the world has to wait while the author devotes his powers to work which a clerk could do nearly as well!

Of these later papers, however, that "On the Long Spectrum of the Electric Light," and particularly those on the "Absorption Spectrum of Blood," are of very great value, the latter especially for their physiological applications.

We must not omit to mention that, partly in conjunction with the late Mr. Vernon Harcourt, Stokes has made a most valuable experimental inquiry into what is called *Irrationality of Dispersion*, chiefly with a view to the further improvement of achromatic telescopes.

He has also proved, by very exact measurements, that the wave-surface for the extraordinary ray in uniaxal crystals is (at least to the degree of accuracy of his experiments) rigorously an ellipsoid of revolution. From the theoretical point of view this is a result of extreme importance; and it is a happy illustration of what we have already said as to the conjunction in Stokes of the experimenter and the mathematician.

Several of his papers are devoted to the extraordinary and, at least at first sight, apparently incongruous properties of the Luminiferous Ether—more especially with the view of explaining (on the Undulatory Theory) the observed Law of the Aberration of Light. He has also reaped an early harvest from the even now promising field of the connection between *Absorption* and quasi-metallic *Reflection* of Light—and has furnished the student with an admirably simple investigation of the *Conduction of Heat in Crystals*.

It is quite possible that, in hurriedly jotting down our impressions and recollections of Stokes' work, we may have omitted something of even greater value than we have recorded. But if so, does the fact not show the absolute necessity that exists for a reprint of all Stokes' works, collected alike from the almost inaccessible *Cambridge Philosophical Transactions*, the ponderous *Philosophical Transactions*, &c., no less than from the *Sitzungsberichte* of the Imperial Academy of Vienna, in which we find Stokes suggesting a preservative for miners against the deadly vapour of mercury?

Stokes was President of the British Association at the Exeter meeting in 1869. The Address he then delivered was a thoroughly excellent and appropriate one; and its modest but firm concluding paragraphs are well calculated to reassure those who may have been perplexed or puzzled by the quasi-scientific materialism of the present day.

P. G. TAIT

SCIENCE EDUCATION FROM BELOW

THE Science Department of the Committee of Council on Education was instituted twenty-two years ago. At that time the general public was far from being alive to its advantages, and for the first seven years it achieved very little. The second term of seven years showed a considerable increase in the number of science schools throughout the country; but it was only during the third septennial period (1867 to 1874) that the importance of such an educational agency became in any sense duly appreciated; and it is not too much to say that it is now one of the most important scientific organisations in this or any country.

Still, in the Government schools as elsewhere, science teaching hitherto has had uphill work, nor must we delude ourselves with the pleasing idea that the road is now all smooth and level. It is true that for some years past the extension of education in this direction has been a popular cry, and a good deal of political capital has been made of it. The international exhibitions have been mainly at the bottom of this; and one of the great benefits derived from those occasions of friendly rivalry has been the diminution of that self-satisfaction which is the greatest bar to progress. Economists have reminded us that we have been relying upon our physical advantages as a nation, rather than the intelligence of our people, in our competition with the rest of the world, and that if we are to maintain our supremacy we must not be behind other nations in the practical applications of knowledge. The argument goes home readily enough to a commercial people, but it is one thing to admit the fact, and another to apply the remedy. The majority of the upper class, from the circumstances of their position and education, are indifferent to the matter. It is foreign to the idea of our older Universities and public schools; and these have exercised, and still continue to exercise, a direct influence over the middle-class schools. True, the number of professional chairs is on the increase, and opportunities are now afforded of practical study in physical and chemical laboratories; but it cannot be pretended that these studies yet take their proper rank amongst the rest. The inferior educational establishments naturally take their cue from the superior ones; indeed, they do so almost as a matter of necessity. They have not only to please the public, but the masters can only impart to their scholars the knowledge they themselves possess; and until on the one hand it be required that the pupils should be taught science, and on the other the masters find it to be an indispensable portion of their educational course, the progress of these studies in private schools will be but slow. In our large towns special teachers can be had for the purpose, but as a fact they are discouraged, the subjects they teach being generally regarded as extras and reduced to a minimum so as not to interfere with the regular routine of the school and the work of the resident masters. So long as the time of the boys is to be wasted in making wretched Latin verses, and the amount of their learning is to be measured by the retentiveness of their memory rather than by how much they understand, the hope of progress in this quarter must inevitably be small.

The operations of the Government department have, however, no direct bearing upon any such schools, unless the principals choose to avail themselves of it as an examining body; but we believe the indirect influence to be already considerable, and likely to become more so in the course of the next few years. Nothing will tend to arouse the proprietors of our boarding schools throughout the land to the necessity of improving both the quantity and quality of the instruction given in them, more than the upward pressure that will be exerted by those who

in a social sense occupy the level immediately below them. The moving impulse is from below, and to that we must now more particularly direct our attention.

From the first the South Kensington establishment has acted as an examining body, and the staff appointed for that purpose includes the names of the most eminent professors in natural and physical science. Subject to certain limitations the passes carry with them pecuniary grants to the authorised local teachers; prizes and medals of honour to the most proficient of the students. The department also makes grants in aid of scholarships and the Royal and local exhibitions, as well as having the administration of those scholarships which were endowed by Sir Joseph Whitworth. Grants are also made in aid of new local schools of science, and towards the cost of the apparatus which they may require. Special classes for the improvement of acting teachers are held by some of the Professors. Lastly, we must not omit to mention in our summary the well-known museum under its management, and the too little known educational library which is available to the general public on payment of a very trifling fee.

The twenty-three branches of study dealt with include Mathematics, Mechanics, Physics, Natural Science, and some of the Applied Sciences. The six most popular among the students are Physical Geography; Pure Mathematics; Animal Physiology; Magnetism and Electricity; Inorganic Chemistry; Acoustics, Light, and Heat: some, such as Navigation and Nautical Astronomy, are, from their very nature, little studied except in special localities. The large preponderance of students in Physical Geography, generally nearly double that of the next in rank, is due to girls' schools, in which it forms a leading feature, being included.

Those who care for statistics will be interested in the following table, for which we are indebted to the courtesy of the Secretary of the Science and Art Department. The table shows the actual state of the Science Classes in Great Britain during the last session.

—	No. of Classes.	No. of Students.	Students examined.
I.—Practical Plane and Solid Geometry.	211	4631	2500
II.—Machine Construction and Drawing.	248	5201	3968
III.—Building Construction.	181	2518	1302
IV.—Naval Architecture.	12	183	117
V.—Mathematics. Stages 1, 2, 3.	537	10502	6228
V.—Mathematics. Stages 4, 5.	18	251	121
V.—Mathematics. Stages 6, 7.	5	23	21
VI.—Theoretical Mechanics.	105	2265	1668
VII.—Applied Mechanics.	66	1238	704
VIII.—Acoustics, Light, and Heat.	357	8463	5473
IX.—Magnetism and Electricity.	485	12515	9122
X.—Inorganic Chemistry.	322	8259	5264
XI.—Organic Chemistry.	49	701	286
XII.—Geology.	162	3183	2598
XIII.—Mineralogy.	15	307	116
XIV.—Animal Physiology.	414	9470	6623
XV.—Elementary Botany.	66	1914	1168
XVI. and XVII.—General Biology.	35	547	209
XVIII.—Principles of Mining.	6	110	95
XIX.—Metallurgy.	10	110	173
XX.—Navigation.	32	537	251
XXI.—Nautical Astronomy.	9	236	92
XXII.—Steam.	73	1260	908
XXIII.—Physical Geography.	686	17720	13312

The students for whom this machinery is designed belong to what may be termed the Industrial Classes, including all those in receipt of weekly wages, small tradesmen whose income does not exceed 200*l.* per annum, the children of any of these, all attendants at Public Elementary Schools, together with the teachers and pupil teachers of such, and the students in the Training Colleges which receive grants from the Education Department. This list of course includes such as constitute our mechanics' institutes and co-operative societies, in the programmes of which science classes now form an important element. In these the practical advantages are of a most direct character; but we are disposed to ascribe a still higher value to the assistance rendered in the Training Colleges and to the acting and pupil teachers in the Public Elementary Schools. Hitherto one of the difficulties which the department has had to contend against has arisen from the unavoidable circumstance that so many of the local science teachers are themselves self-taught, and their deficiencies have often been only too apparent in the character of the examination papers given in by their pupils: time, however, will do much to cure this as these teachers drop into the background and are succeeded by those who have gone through a systematic training.

The next table will show the rapid extension of the operations of the department during the years 1867 to 1873 inclusive. It will be seen, on comparing the figures, that the relative number of those who now go up for examination is greater than formerly, and that the increase in the number of papers worked is still greater in proportion.

Year.	Number of Science Scholars.	Number who went up for Examination.	Number of Examination Papers worked by them.	Number of Papers passed.
1867	10,230	4,520	8,213	6,013
1868	15,010	7,092	13,112	8,649
1869	24,865	13,234	24,085	14,550
1870	34,283	16,515	34,413	18,690
1871	38,015	18,750	38,098	22,105
1872	36,783	19,568	39,383	27,806
1873	48,546	24,674	56,577	35,100

It is abundantly clear then that through the enlightened and vigorous action of the Science and Art Department, a large bulk of the population of our country has received and is receiving an elementary scientific education. The work which Sir Henry Cole began can no longer be sneered at nor overlooked; its value to this country is beginning to be widely recognised, and the man who laid its foundations so wisely and well deserves the highest gratitude of his countrymen. Let us remember that only a few years ago there was little science education in the higher classes, and absolutely none in the lower; whereas, scattered over Great Britain, there are in active work this year no less than 1,707 certificated science teachers engaged in 1,374 science schools, teaching 4,104 separate classes, and the number of individuals actually receiving science instruction by this means reaches the enormous total of 48,274.

The Department, however, has not been content to rest on its laurels. Within the last few years it has undertaken a new work, which promises to be of the highest value. It was felt that the system of examinations needed supplementing. Teachers could gain certificates, and thus receive payment upon the results of their teaching, without any evidence of their having more than book knowledge. And it was found, indeed, that the great body of certificated teachers had, with few exceptions, little practical knowledge of the various subjects they taught. They could accurately describe an electrophorus, but they could not make one, nor use it perhaps when made; they knew all about the circulation of the blood or the structure of the heart, but they had never seen the one nor dissected the other. For the most part they knew nature as words, not as living facts. The eminent men who conduct the examinations for the Department saw the danger that was arising. Prof. Huxley addressed the Government upon the subject, and urged a practical class in Physiology for a certain number of science teachers certificated in that subject. By taking fresh men each year it was hoped that a large amount of practical knowledge would be diffused and gradually make its way through the various science classes. The late Government promptly acceded to the wish thus expressed, and in 1869 two short practical courses of a week each were given, the one on Animal Physiology and the other on Light.

The importance of even such brief instruction was so manifest that it was decided to enlarge the original conception. The details of the scheme were, however, difficult and needed to be grappled with in earnest. The body of teachers was large and distributed over wide areas; they could not afford the time nor money to come to London for instruction, and even if they had the requisite knowledge their means were too slender to enable them to purchase the apparatus needed for the proper demonstration of their subject. To the administrative genius of Major Donelly, the present chief of the Science Staff at South Kensington, no less than to his untiring zeal in the cause of scientific education, the country is mainly indebted for the solution of this formidable difficulty. Announcements were made to all the certificated science teachers throughout the country that a month or six weeks' gratuitous course of daily practical instruction, in various branches of experimental science, would be held at the new Science Schools at South Kensington during the summer vacation. Those who wished for this instruction were to apply to the Department; if selected, their expenses to and from London would be paid, and thirty shillings a week given to each as a maintenance allowance whilst they remained in London. It was soon found imposssible to accommodate all who applied; at present the applications are about three times as many as can be taken. In the selection of the men most needing this kind of instruction, and who would afterwards make the best use of it, arose another difficulty. But, as before, the excellent judgment of the Secretary of the Science and Art Department, and the careful scrutiny of his officers, led to a choice of such capital men that the wisdom of their mode of selection has been shown in the happiest manner.

At the present moment sixty teachers are working at Practical Chemistry under Prof. Frankland and Mr. Valentin; thirty-one teachers are studying Heat practically under Prof. Guthrie; these have been preceded by the same number who have worked at Light; twenty-one are studying Mechanics with Professors Goodeve and Shelley; twenty-eight are being taught Geometrical Drawing by Prof. Bradley; and thirty-eight are working at Machine Construction and Drawing under Prof. Unwin.

The applicants give a list of the courses they wish to attend, in much the same way that one hands in a selected list of books to Mudie's Library; they are allotted courses as far as possible in their order of preference, and may, in successive years, take successive subjects. The courses only last from three to six weeks. Chemistry this year runs on from the 1st to the 23rd of July; Physics, from June 23rdto Aug. 3rd; Mechanics and Geometrical Drawing from June 30th to July 22nd; and Machine Construction from 27th July to13th of August. It might be imagined that such short courses could be of little real use; experience has, however, shown the reverse. The fact is, the men in each subject are thirsting for information, they know they have now a chance which may never recur to them; in a few short weeks they must strive to win much knowledge, which they not only desire for its own sake, but which means bread and cheese to their families. They are prompted, therefore, by every inducement to make the best possible use of their time. It is this heartiness of work combined with the admirable system of instruction given by each professor that has made these short summer courses so remarkably effective.

Capital evidence of the value of what is being done may be had by simply walking through the different rooms of the Science Schools and observing the teachers at work. If, for example, we go into the Biological department,* we find every man busily dissecting plants or animals, each one seated at a separate little table, and each provided with an excellent microscope and proper instruments and suitable specimens. The earnestness of everybody in the room strikes one very forcibly; and as we look at the fresh specimens at every table, we think of the labour implied in choosing typical objects and securing forty or fifty of each daily. Professors and students unquestionably are hard at work. If we now go into the fine chemical laboratories a like impression is produced. Here are one set making perhaps their first

practical acquaintance with the reactions which they have so often written down, and which in future they will regard with an altogether new interest and delight. Others more advanced are conducting analyses, or perhaps making "combustions"—if in the advanced group, studying organic chemistry. All are intensely busy, and work with a fixed purpose before them. The same quiet activity is noticeable in the different subjects going on in the other rooms. Entering last the physical laboratory on the ground floor, we find the teachers constructing apparatus which, though simple and often rough, is well adapted for teaching purposes. The raw material is provided them, printed instructions are given to each one, and under the direction of Prof. Guthrie, and the gentlemen associated with him, the most useful physical instruments are built up. These instruments are then employed in repeating the experiments seen in the morning lecture, or in making physical measurements wherever it is possible to do so. The homely apparatus, it is true, has not the polish of the instrument-maker, but in delicacy and efficiency is, generally speaking, far better than the teachers could purchase out of the small grants allowed to them for that purpose. With a wise liberality the Department permits each teacher to take home with him, without any charge, all the apparatus he himself has made: and one can easily imagine the pleasure with which these simple and useful instruments are afterwards looked upon and used by those who have made them. Nor is this all; the impulse to sound and practical science teaching is given, and at the same time the hands have been disciplined to useful skill, and the senses trained to accurate observation. After such preparation good use is made by the teachers of the more refined physical instruments which are set before them, but which are beyond their time or power to construct for themselves. It is most instructive to watch one of these men as he makes his first essay, and to trace the growth of his education in manipulative skill and in practical knowledge of his subject. We propose in our next number to go more fully into detail in this matter, and to describe some of the simple physical apparatus made by the teachers.

But the good work done by the Department does not rest here. In addition to giving practical instruction to teachers in short summer courses, free admission to extended courses of lectures and practical instruction in Chemistry, Physics, Mechanics, and Biology at South Kensington was granted to a limited number of teachers and students who intended to become science teachers. The selected candidates received a travelling allowance, and a maintenance allowance of 25*s.* a week while in London. The courses in Chemistry and Biology commenced in October of last year and ended in the early spring, when the courses in Physics and Mechanics began, and these closed at the beginning of this summer. From ten to sixteen teachers in training attended these different classes, and worked daily from 10 to 5 at the subjects they had chosen, in the evening writing up their notes and memoranda. Botany was not included in the foregoing series, but it was not forgotten. In January last the Lords of the Committee of Council on Education gave directions for a practical course on this subject. The course was given by Prof. Thiselton Dyer, and commenced on the 4th of March last, extending over eight weeks. It was attended by twenty-three science teachers and persons intending to become science teachers; these received precisely the same advantages as the teachers in training in the other subjects.

The value of such courses as these can hardly be overestimated, and we trust that no niggardly policy will lead the Government to restrict the great and good work they have begun. We hope there is no cause for apprehension in the apparent neglect of Biology in the summer course given this year, and what seems to us a little diminution of the strength of the staff in another subject. The improvement in the quality of the education given by the science teachers is already making itself felt. The reports of the May examiners for recent years show that "while the general average has been maintained throughout, the instruction had in some subjects decidedly improved." But it will necessarily take a few years to lift up so large a constituency. Surely and slowly it is being done, and the masses of the country are gaining a sound elementary knowledge of science. Whilst the magnificent laboratories of the Universities of Oxford and Cambridge and Dublin are nearly empty, Owens College and the classes under the Department are crowded with active and earnest workers.

The several large educational societies of England have availed themselves for some years past of the benefits offered by the Science and Art Department, with the object of turning the students out of their Training Colleges as thoroughly fitted as possible for their future scholastic career; and the continuance of this system for the future is now further assured by the necessity of their being provided with Government certificates in science in order to secure employment under the London School Board, or indeed at any of the first-class Elementary Schools throughout the country.

An impartial view of the facts we have placed before our readers will show that what the Universities might have done from above, others are doing from beneath. Science, instead of forming the delightful pursuit of the leisure classes, and thence distilling downwards to the workers, is, on the contrary, first becoming an integral part of the education of the toilers of the country. England, in fact, is being scientifically educated from below.

* This refers to last year; the teachers' summer course on Biology has been omitted this session.

DARWIN ON CARNIVOROUS PLANTS

I.

Insectivorous Plants. By Charles Darwin, M.A., F.R.S., &c. With Illustrations. (London: J. Murray, 1875.)

TO have predicted, after the publication of Mr. Darwin's works on the Fertilisation of Orchids and the Movements and Habits of Climbing Plants, that the same writer would hereafter produce a still more valuable contribution to botanical literature, characterised to an even greater extent by laborious industry and critical powers of observation, and solving or suggesting yet more important physiological problems, would have seemed the height of rashness. And yet, had such a prediction been made, it would have been amply justified by the present

volume, one which would alone have established the reputation of any other author, and which will go far to redeem our country from the charge of sterility in physiological work. Much attention has been called recently to the singular subject of "carnivorous plants;" we have had records of useful original work from several quarters in England, the Continent, and America, together with much that has been superficial and worthless; and even the newspapers have discussed the anti-vegetarian habits of some vegetables in the light, airy, and philistine manner in which they are wont to approach "mere scientific" subjects. During the whole of this time, foi the last fifteen years, Mr. Darwin has been steadily and quietly at work, collecting materials and recording long series of observations; and now at length has given us their results, completely and finally settling some of the points that have been most in controversy, and raising others which suggest conclusions that will take by surprise even those whose minds have been most open to deviate from the old and narrow paths.

Rather more than one-half of the volume is devoted to the most abundant and readily obtainable of these predatory plants, the common Sundew, *Drosera rotundifolia*; and an epitome of this portion must be first placed before our readers.

Commencing with a description of the well-known leaves and their glandular appendages, or "tentacles," as he terms them, Mr. Darwin has arrived at the conclusion that these latter most probably existed primordially as glandular hairs or mere epidermal formations (trichomes), and that their upper part should still be so considered; but that their lower portion, which alone is capable of movement, consists of a prolongation of the leaf; the spiral vessels being extended from this to the uppermost part. One point which seems to be clearly established is, that it is not sufficient that the substance which excites the movements of the tentacles should merely rest on the viscid fluid excreted from the glands; it must be in actual contact with the gland itself. A statement made by several previous observers (including Prof. Asa Gray on the authority of Mr. Darwin's earlier observations, and the present writer)—that inorganic substances are almost or entirely without effect in producing movement—must now be modified. Although the effect is much less considerable, and the substance is soon released from the embrace of the tentacles; yet such bodies as minute particles of glass undoubtedly possess the power of irritation. While it is the glands or knobs at the extremities of the tentacles, and a very small part of the upper portion of the pedicels, which alone are sensitive or irritable, the actual inflection takes place only in the lowermost portion of the pedicel, causing a bending of the tentacle; and the irritation is conducted from the tentacle actually excited to the neighbouring ones, or to all those on the leaf, in such a manner as to cause them to bend towards the object which produces the excitement. One of the most striking of the series of observations here recorded is that which describes the affixing of exciting particles on glands at two different portions of a leaf of *Drosera*, the result being that all the tentacles near each of these two points were directed towards them, "so that two wheels were formed on the disc of the same leaf, the pedicels of the tentacles forming the spokes, and the glands united in a mass" over the irritated tentacle which represented the axle; the precision with which each tentacle pointed to the irritating particle was wonderful. What makes this result the more extraordinary is that "some of the tentacles on the disc, which would have been directed to the centre had the leaf been immersed in an exciting fluid (as in Fig. 1), were now inflected in an exactly opposite direction, viz., towards the circumference. These tentacles, therefore, had deviated as much as 180° from the direction which they would have assumed if their own glands had been stimulated, and which may be considered as the normal one." As the author remarks, "we might imagine that we were looking at a lowly organised animal seizing prey with its arms." Indeed, the whole description of Mr. Darwin's researches after the tissue that conducts this irritation reminds one of experiments on the motor and sensitive nerves of animals; and we commend the subject to the serious attention of the Royal Commission now sitting to investigate the subject of vivisection. Mr. Darwin compares this movement to the curvature displayed by many tendrils towards the side which is touched; but the comparison appears to us to fail, from the fact that the movement of tendrils is a function of growth, they being sensitive to contact or pressure only so long as they are in a growing state; which is not the case with the tentacles of *Drosera*. One of the most extraordinary of the statements made by trustworthy observers with regard to the sensitiveness of these tentacles is not, however, confirmed by Mr. Darwin. Mrs. Treat (*American Naturalist*, Dec. 1873) asserts that when a living fly was pinned at a distance of half an inch from the leaves of the American species *D. filiformis*, the leaves bent towards it and reached it in an hour and twenty minutes, a phenomenon inexplicable on any theory which would account for the transmission of the irritation from one tentacle to another. Mr. Darwin states, on the contrary, that when pieces of raw meat were stuck on needles and fixed as close as possible to the leaves, but without actual contact, no effect whatever was produced. The minuteness of the solid particles which produced sensible inflection was a matter of great surprise. Particles perfectly inappreciable by the most sensitive parts of the human body, as the tip of the tongue—a fragment of cotton weighing $\frac{1}{8000}$, and of hair weighing $\frac{1}{78000}$ of a grain—caused the tentacles with which they were in contact to bend. Our author remarks that "it is extremely doubtful whether any nerve in the human body, even if in an inflamed condition, would be in any way affected by such a particle supported in a dense fluid, and slowly brought into contact with the nerve; yet the cells of the glands of *Drosera* are thus excited to transmit a motor impulse to a distant point, inducing movement;" and he adds justly, that "hardly any more remarkable fact than this has been observed in the vegetable kingdom." The only substance which appears to be altogether without effect in producing inflection is drops of rain-water; a singular exception paralleled by the case of certain climbing plants whose excessively sensitive tendrils are irritable to every sort of object which touches them except rain-drops.

The inflection of the base of the tentacle is accompanied by a change in the molecular condition of the

protoplasmic contents of the cells of the gland and of those lying immediately beneath it; though the two phenomena are not necessarily connected with one another. If the tentacles of a young but mature leaf that has never been excited or become inflected, are examined, the cells forming the pedicels are seen to be filled with a homogeneous purple fluid, the walls being lined with a layer of colourless circulating protoplasm. If a tentacle is examined some hours after the gland has been excited by repeated touches, or by an inorganic or organic particle placed on it, or by the absorption of certain fluids, the purple matter is found to be aggregated into masses of various shapes suspended in a nearly or quite colourless fluid. This change commences within the glands, and travels gradually down the tentacles; and the aggregated masses of coloured protoplasm are perpetually changing

FIG. 1.—(*Drosera rotundifolia.*) Leaf (enlarged) with all the tentacles closely inflected, from immersion in a solution of phosphate of ammonia (one part to 87,500 of water).

FIG. 2.—(*Drosera rotundifolia.*) Leaf (enlarged) with the tentacles on one side inflected over a bit of meat placed on the disc.

their form, separating, and again uniting. Shortly after the tentacles have re-expanded in consequence of the removal of the exciting substance, these little coloured masses of protoplasm are all re-dissolved, and the purple fluid within the cells becomes as homogeneous and transparent as it was at first. This process of aggregation is independent of the inflection of the tentacles and of increased secretion from the glands; it commences within the glands, and is transmitted from cell to cell down the whole length of the tentacles, being arrested for a short time at each transverse cell-wall. The most remarkable part of the phenomenon is that even in those tentacles which are inflected, not by the direct irritation of their glands, but by an irritation conducted from other glands on the leaf, this aggregation of the protoplasm still commences in the cells of the gland itself.

Some who admit the reality of the phenomena now described, have still doubted the digestive power ascribed to the leaves of the Sundew, believing that the apparent absorption of the organic substances in contact with the glands is due rather to their natural decay. This question is, however, entirely set at rest by Mr. Darwin's observations. The action of the secretion from the glands on all albuminous substances—for it is by these only among fluids that inflection of the tentacles is excited—is precisely the same as that of the gastric juice of animals. The secretion of the unexcited glands is neutral to test-papers; after irritation for a sufficiently long period it is distinctly acid. A very careful analysis by Prof. Frankland of the acid thus produced indicated that it was probably propionic, possibly mixed with acetic and

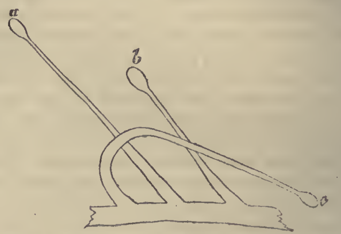

FIG. 3.—(*Drosera rotundifolia.*) Diagram showing one of the exterior tentacles closely inflected; the two adjoining ones in their ordinary position.

butyric acids; and the fluid, when acidified by sulphuric acid, emitted a powerful odour similar to that of pepsin. If an alkali is added to the fluid, the process of digestion is stopped, but immediately recommences as soon as the alkali is neutralised by weak hydrochloric acid. Mr. Darwin believes that a ferment of a nature resembling that of pepsin is secreted by the glands, but not until they are excited by the absorption of a minute quantity of already soluble animal matter; a conclusion which is confirmed by the remarkable fact observed by Dr. Hooker, that the fluid secreted by the pitchers of *Nepenthes* entirely loses its power of digestion when removed from

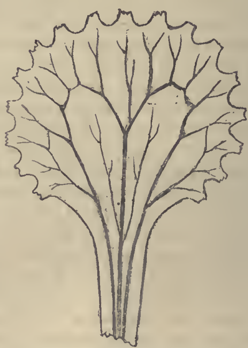

FIG. 4.—(*Drosera rotundifolia.*) Diagram showing the distribution of the vascular tissue in a small leaf.

the pitcher in which it is produced. It is one of the many extraordinary facts connected with this subject that the tentacles of the leaves of *Drosera* retain their power of inflection and digestion long after the separation of the leaves from their parent plant.

As might naturally be expected, salts of ammonia are among the substances which have the most powerful effect on the leaves of *Drosera*; but the excessively minute quantities which are efficacious will probably be

as astonishing to everyone else as they were to Mr. Darwin himself. From a most carefully conducted series of experiments from which every possible source of error seems to have been eliminated, it appears that the absorption by a gland of $\frac{1}{268800}$ of a grain of carbonate of ammonia (this salt producing no effect when absorbed through the root) is sufficient to excite inflection and aggregation of the protoplasm. With nitrate of ammonia a similar effect is produced by the $\frac{1}{691200}$ of a grain; while the incredibly small quantity of $\frac{1}{19760000}$ of a grain of phosphate of ammonia produces a like effect. Mr. Darwin believes that carbonate of ammonia is also absorbed in the gaseous state by the tentacles; but we venture to think that the evidence on this point is not conclusive. In both the experiments which he records the air surrounding the plant was more or less humid, and the effect was much more intense in the one where the air was the dampest, indicating apparently that the inflection was due to the absorption of the extremely soluble gas by the moisture which was in contact with the tentacles. This would also afford an explanation of what he regards as "a curious fact, that some of the closely adjoining tentacles on the same leaf were much, and some apparently not in the least, affected," if we suppose that they were clothed with larger and smaller amounts of moisture. The view that the glands have no power of absorbing gases or effluvia receives confirmation from the failure of the attempt to induce inflection or aggregation by the affixing of particles of meat in close proximity to the tentacles, but without actual contact.

We cannot follow Mr. Darwin through his exhaustive series of experiments on the effects of various solutions of mineral salts, acids, and poisons, on the leaves of *Drosera*. With organic fluids the aggregation of the protoplasm and inflection of the tentacles furnish a most delicate and unerring test of the presence of nitrogen. The effect of inorganic salts and poisons can by no means be inferred from the effect of the same substances on living animals, nor from their chemical affinity. Nine salts of sodium all produced inflection, and were not poisonous except when given in large doses; while seven of the corresponding salts of potassium did not cause inflection, and some of these were poisonous. This corresponds to the statement of Dr. Burdon Sanderson, that sodium salts may be introduced in large quantities into the circulation of mammals without any injurious effects, whilst small doses of potassium salts cause death by suddenly arresting the movements of the heart. Benzoic acid, even when so weak as to be scarcely acid to the taste, acts with great rapidity and is highly poisonous to *Drosera*, although it is without marked effect on the animal economy. The poison of the cobra, on the other hand, so deadly to all animals, is not at all poisonous to *Drosera*, although it causes strong and rapid inflection of the tentacles, and soon discharges all colour from the glands.

The last point of investigation is the mode of transmission and nature of the conducting tissue of the motor impulse from one tentacle to another. It has been already stated that the seat of irritability is limited to the glands themselves and a few of the uppermost cells of the pedicels, the blade of the leaf itself not being sensitive to any stimulant. In order to be conveyed from one tentacle to another, the impulse has therefore to be transmitted down nearly the whole length of the pedicel; and it appears to be conveyed from any single gland or small group of glands through the blade to the other tentacles more readily and effectually in a longitudinal than in a transverse direction. It can be shown that impulses proceeding from a number of glands strengthen one another, spread further, and act on a larger number of tentacles than the impulse from any single gland. The phenomenon already alluded to, of the aggregation of the protoplasm in a tentacle incited indirectly by the irritation of other glands on the leaf—this aggregation advancing not upwards, but downwards, in each tentacle—is spoken of by Mr. Darwin as partaking of the nature of those actions which in the nervous systems of animals are called reflex. The existence of such a phenomenon—of which this is the only known instance in the vegetable kingdom—is one of the most extraordinary points brought out by these investigations. It will be recollected that the transmission of the motor impulse in the sensitive leaves of *Mimosa* is in a precisely opposite direction, travelling upwards from the base to the apex of those pinnæ which are indirectly irritated in consequence of the direct irritation of other pinnæ of the same leaf. The arrangement and direction of the fibro-vascular bundles in the leaves of *Drosera* are shown in Fig. 4; and Mr. Darwin's inquiries were first directed to solve the question whether the impulse was conveyed through the vascular system; but he came to the conclusion that it is not sent, at least exclusively, through the spiral vessels or through the tissue immediately surrounding them. He believes, on the contrary, that the conducting tissue is the parenchyma or cellular tissue of the mesophyll of the leaf; and that it is chiefly delayed by the obstruction offered by the cell-walls through which it has to pass; the transmission of the impulse being indicated by the phenomenon of aggregation of the protoplasm, which is transmitted gradually from cell to cell.

A few other species of *Drosera* were examined, but presented no special phenomena of interest; and the remainder of the volume is occupied by the narrative of researches on other carnivorous plants, a review of which we must defer to a future number.

ALFRED W. BENNETT

(*To be continued.*)

PERCY'S METALLURGY

Metallurgy: Introduction, Refractory Materials and Fuel. By John Percy, M.D., F.R.S. (London: J. Murray, 1875).

THIS valuable work is not merely a new edition of the volume previously published by its distinguished author, for it contains more than 350 pages of fresh matter, and several articles on subjects which were not treated of originally. Dr. Percy's "Metallurgy" is so well known as the standard book in this country that it may be well to indicate as succinctly as possible the differences between the present volume and the portion of the one published in 1861, which was devoted to refractory materials and fuel.

Much information has been added to the section which

treats of the physical properties of metals. Thus a general but comprehensive view of the subject of Elasticity is given, with ample references to the works of Wertheim, Kupffer, Styffe, and others. Tresca's experiments on the flow of metals are also briefly described, and "Tensile strength" has received due attention. Graham's experiments on the occlusion of gases by metals are described at some length.

The matter relating to the composition, fusibility, and character of slags, has been re-arranged.

As plumbago crucibles are now so extensively used, the question of the suitability of different kinds of graphite for their manufacture has become of much importance. A valuable table of analyses of graphite of various qualities from different localities is therefore given, and the machinery used by Messrs. Morgan in their well-known crucible works is illustrated by excellent drawings. The apparatus devised by Ste. Claire Deville for obtaining high temperatures is now frequently employed in laboratories, and the description of the methods of making the crucibles of carbon, lime, magnesia, alumina, and bauxite will be of much service. Deville's blast furnace is described, but we could have wished that, in the interests of metallurgical research, some account had been given in this place of the oxyhydrogen blowpipe, and of the apparatus by means of which he melted platinum.

Care has been taken to collect the recently discovered facts relative to the calorific power and calorific intensity of fuel, and these are specially considered with reference to furnace temperatures. The section devoted to Pyrometry is excellent, and Weinholt's classification of the principles on which the instruments have been constructed has been adopted.

The question of the utilisation of peat and of the possibility of substituting it for coal in metallurgical and other manufacturing processes, has of late particularly engaged public attention in this country. Dr. Percy has therefore collected "such evidence as may enable the reader to arrive at a satisfactory judgment on that question," and forty-six pages are devoted to the consideration of cutting peat, together with its mechanical treatment, condensation, and desiccation. We may quote some of Dr. Percy's general conclusions as to its use as fuel. He observes that, "so far as the suitability of peat for metallurgical purposes is concerned, we may not unreasonably conclude that it could be widely substituted for coal with success;" but he states as his conviction that peat can only compete with coal in countries where the cost of production and carriage of peat is relatively very low and the price of coal is relatively very high.

More than 200 analyses of coal from various parts of the world are given, and we may mention as an indication of the care which has been taken to render the section devoted to coal as complete as possible, that Von Meyer's recent investigations as to the nature of the gases disengaged from certain varieties, and Fleck's table showing the action of weathering on the chemical composition of coal, are recorded at some length. Valuable remarks as to the various sources of error in the analysis of coal are given, but we venture to think that students would have been grateful for some account of the methods of analysis and details of manipulation.

The author next treats of charcoal, and an account of Dromart's process for charring in circular piles by firing at the bottom has been added to the descriptions of the various processes contained in the former volume. Reference is also made to the methods of preparing brown charcoal and "torrefied wood," and the section concludes with theoretical considerations concerning their use.

In the new matter relative to coke, the various methods of desulphurisation are treated at some length, and, in considering the economic products generated during coking, Dr. Percy gives much evidence as to the working of Pernolet's oven; but he concludes, as in the case of many other metallurgical operations, by pointing out that the evidence as to the advantages of the process "is not a little conflicting." A new article has been added on the preparation of peat-charcoal, with reference to the employment of which the author observes "that as yet the use of peat-charcoal in metallurgical operations in Great Britain is either very restricted or must be kept rigidly secret."

The consideration of one or two questions of practical importance in connection with the subject of fuel is reserved for the conclusion of the volume.

The author, in treating of the preparation of peat for fuel, makes some observations on patents generally which deserve notice. He says: "Should any person of ordinary intelligence be disposed to wade through the dreary specifications of patents relating to the preparation of peat for fuel, he will perceive that frequently the same thing has been patented several times, and that in not a few cases the patentees have displayed astounding ignorance of the subject." He suggests as a remedy that "a tribunal for the administration of patent law" should be established. "The expenses of such a tribunal could be defrayed . . . . out of the large *surplus* income, exceeding 50,000*l*., arising from the duties and fees paid by patentees." The authority of such a court would doubtless have a very beneficial effect; but we may point out that the sum above named would probably be very materially reduced by its intervention, and that the vigilance and remuneration of the tribunal might each tend to diminish the other. Dr. Percy calls attention to the scheme proposed during the present session by the Lord Chancellor, who suggests the appointment of five additional commissioners of patents, without giving them any remuneration whatever for their services!

Among the illustrations are plans and sections of Ekman's peat kiln, of Echement's pile for making brown charcoal, and at the end of the volume there are nine folding plates, some of them coloured, giving complete working drawings of Siemens' gas producer and regenerative gas reheating furnace, and of Coppée's coke oven, in which even the forms and dimensions of the fire-bricks are shown. The drawings throughout the volume are admirable, and, as is the case in all Dr. Percy's works, are drawn to scale.

We think that it is a matter for congratulation that the author's labours have been devoted to rendering the introduction to Metallurgy as complete as possible, before considering metals not yet touched upon, which would doubtless have been more attractive work. Throughout this, as in former volumes, the slightest aid has been carefully acknowledged, and the relative merits of discoverers are most conscientiously apportioned, in Dr.

Percy's remarks, which are sometimes severe but always impartial.

In viewing the volume in relation to metallurgical science generally, we are reminded of a remark made by Dumas more than twenty years ago: "Les nouvelles substances métalliques ne méritent certes pas l'oubli dans lequel les chimistes les laissent depuis si longtemps." We fear that the words apply with some force to the state of metallurgical *research* at the present day; still, the progress which has been made is very considerable, and this country has good reason to be proud of Dr. Percy's contributions to the literature of the subject.

OUR BOOK SHELF

Sound. By John Tyndall, D.C.L., LL.D., F.R.S., Professor of Natural Philosophy in the Royal Institution of Great Britain. Third Edition. (London: Longman and Co., 1875.)

THE principal addition to this new edition of Dr. Tyndall's work on Sound is an account of the investigation which he has conducted in connection with the Trinity House, and which he treats here under the title, "Researches on the Acoustic Transparency of the Atmosphere, in relation to the question of Fog-signalling." By this investigation, "not only have the practical objects of the inquiry been secured, but a crowd of scientific errors, which for more than a century and a half have surrounded this subject, have been removed, their place being now taken by the sure and certain truth of nature." In his preface Dr. Tyndall remarks on some of the criticisms which have been made on the results of the investigations referred to. It is interesting to learn that the work has been translated into Chinese, and published at the expense of the Government at the moderate price of 20*d.*

Six Lectures on Light, delivered in America in 1872-73. By John Tyndall, D.C.L., F.R.S., &c. Second Edition. (London: Longman and Co., 1875.)

WE are glad to see that these interesting popular lectures, to which we referred during and after their delivery, have reached a second edition; they are well calculated to interest the general reader, and, we have no doubt, have been the means of inducing many to make a systematic study of the subject to which they refer. The principal change in this edition is the omission of Dr. Young's "Reply to the Edinburgh Reviewers," the reprint of which in the first edition, Dr. Tyndall believes, has served the purpose intended. In place of this, a beautifully executed steel engraving of Lawrence's portrait of Young is prefixed to the volume.

The Birds and Seasons of New England. By Wilson Flagg. With Illustrations. (Boston: Osgood and Co. London: Trübner and Co., 1875).

MR. FLAGG is evidently an enthusiastic lover and close observer of nature in all her moods and phases, but this more from the sentimental and poetic than from the scientific point of view. His book consists of a great number of essays on various aspects of nature as manifested in the New England country, the most original being on the songs of the birds of that region. That he must be a very patient and very minute observer is evidenced by the fact that he has actually embodied in musical notation the songs of some of the principal singing birds of New England. We have no means of testing the correctness of Mr. Flagg's interpretation of these singers, but we should think, judging from the very careful observations he has evidently made, that they are generally correct. The work also contains essays on the aspects of nature in the various months of the year, and on such subjects as "The Haunts of Flowers," "Water Scenery," "The Field and the Garden," "Picturesque Animals," "The Flowerless Plants," "Swallows: their Hibernation," "Changes in the Habits of Birds," &c. Mr. Flagg's essays, we must say, are on the whole rather tedious, reminding us often of the tiresome moral essayists of last century, although they frequently contain passages of quite poetic beauty. There is also a sufficient amount of novelty about many of the subjects to add interest to his observations, and many facts are recorded concerning the habits of the New England birds that will give the book some value in the eyes of the naturalist. Those who love a quiet dreamy country life will find much throughout the book to interest them. Mr. Flagg, as we have said, evidently possesses the power of minute observation, and we would recommend him to bring himself abreast of the ornithology, and indeed general natural history, of the day, and carry on his observations from a more scientific point of view, which he can easily do, and still find scope enough for the satisfaction of his sentimentalism; he might thus render substantial service to science. Judging from what he says about the "hibernation" of swallows, he seems to be unaware that anything has been written on the subject of the migration of birds since the days of Gilbert White. Mr. Flagg's essays want the simplicity and naturalness and geniality of the Letters of that minute observer.

The illustrations of New England scenery are beautiful specimens of the heliotype process, and add much to the interest of the work. An index is appended containing both the common and the scientific names of the birds referred to in the work, but why should so carefully "got-up" a book have been printed without a table of contents?

Practical Guide to Carlisle, Gilsland, Roman Wall, and Neighbourhood. By Henry Irwin Jenkinson. Also, *Smaller Practical Guide.* By same author. (London: Edward Stanford, 1875).

MR. JENKINSON has succeeded in accomplishing what he has aimed at; he has written a really "useful, entertaining, and instructive" guide-book to the district indicated in the title. This district, of no very great extent, abounds in varied interest, and to those who desire to visit it we could recommend no more valuable companion than Mr. Jenkinson's "Practical Guide." He has evidently taken pains to make himself personally well acquainted with the localities he describes, and has diligently collected all the historical and other associations which add interest to the various points to be visited. To antiquaries, his "Walk along the Roman Wall from Coast to Coast" will be specially interesting, and with this book in one's hand we could imagine no more interesting and instructive walk for a summer holiday. The difference between the larger and smaller Guide is, that the former contains an additional eighty pages on the Local Names and the Natural History—Geology, Mineralogy, Botany, Entomology, and Ornithology—of the district, which adds to its value from a scientific point of view. Both books contain an excellent map of the county from coast to coast, embracing a distance of several miles on each side of the Roman Wall. We commend the Guide as the best to be had for the district to which it refers.

North Staffordshire Naturalists' Field Club. Annual Addresses, Papers, &c. With Illustrations. (Hanley: William Timmis, 1875.)

THIS club has now been in existence for ten years, and judging from the list of papers read and excursions made, has evidently carried out with creditable faithfulness the

object for which it was established—the study of the natural history and antiquities of the neighbourhood. The volume before us contains a selection of some of the principal papers read at the Club meetings during these ten years, and, as a whole, they reflect credit on the diligence, intelligence, and knowledge of the authors. Both the papers on general and those on local subjects contain much valuable material, quite deserving of publication, and the latter especially will be useful to those who want information on the natural history and antiquities of Staffordshire. One of the most interesting general papers is by Dr. J. Barnard Davis, "On the Interments of Primitive Man," which is illustrated by some beautifully executed woodcuts. Of the papers on local subjects, we may mention "Notes on the Fossil Trees in a Marl Pit at Hanley," by John Ward, F.G.S.; "The Geology of Mow Cop, Congleton Edge, and the surrounding district," by J. D. Sainter, F.G.S.; "On the absence of Waterfalls in the Scenery of North Staffordshire," by J. E. Davis; and "On the Organic Remains of the Coal Measures of North Staffordshire," by John Ward, F.G.S. Appended is a considerable list of Macro-Lepidoptera taken and observed in North Staffordshire by members of the Club, by T. W. Daltry, F.L.S. The illustrated paper on Croxden Abbey is a valuable one of its kind.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

The India Museum

In your notice of the various transfers of the India Museum (vol. xii. p. 192), you do not allude to the somewhat important fact that from 1869 up to the recent opening of the new museum the whole of the Natural History Collections have been kept in closed boxes in the cellars of the India Office.* This has been a grievous wrong to working naturalists, who have constantly required access to typical specimens to solve various points of inquiry.

Again and again the attention of the authorities of the India Office was called to this state of affairs without effect, and naturalists cannot give too much credit to Lord Salisbury and the present Administration for putting an end to the scandal that existed so long.

Unfortunately, however, as I prophesied, it has been found on opening the boxes that some of them have been attacked by moth, and that valuable specimens have perished.

July 9 P. L. Sclater

Irish Cave Exploration

During the last few weeks Dr. Leith Adams, F.R.S., and myself have been exploring an ossiferous cave at Shandon, near here, under a grant from the Royal Irish Academy. Bones of mammoth, reindeer, bear, wolf, horse, and hare, were found in the *débris* of a quarry here in 1859, and are now in the Royal Museum, Dublin. We have worked through a considerable quantity of limestone breccia and stalagmite, in which and in a thin underlying deposit of cave-earth we have found numerous bones of the above-mentioned animals, indicating at least two individuals of mammoth, eighteen of reindeer, and five of horse, for which latter this is as yet the sole recorded locality in Ireland. The bones of bear show extreme age and signs of disease, and we have found the cast antler of a reindeer. Some of the bones have been gnawed, probably by wolves, and many have been broken by the falling-in of the roof of the cave. Though we have broken into a large chamber, we are as yet unable to form a clear conception of the original form of the cavern. A full account of the cave previous to the present exploration was given by Prof. Harkness in the *Geological Magazine* for June, 1870. G. S. Boulger

Dungarvan, Co. Waterford, July 11

* See Nature, vol. vii. p. 457.

Sea-power

Will you allow me to ask your readers one or two questions upon a subject which may ultimately belong rather to an engineering than to a purely scientific journal, but which at present has not, I believe, passed into the hands of practical men? I wish to know:

1. Where—if anywhere—use is made of the movements of the sea as motive powers?

2. Where I can find the latest and fullest information upon this subject?

I have an impression that a paper on the subject appeared in one of the volumes of Nature, but I cannot find it. The latest paper on which I can now put my hand is M. Cazin's lecture on "Les Forces Motrices," in the *Revue des Cours Scientifiques* of Feb. 19, 1870. The lecturer mentions the failure of the *moulins de marée*, and gives a description, with diagram, of M. Tommasi's proposed *flux moteur*.

It has long appeared to me that the immense importance of the question as to the possibility of utilising sea-power has not been sufficiently recognised. The practical solution of this question would not only give to England an inexhaustible motive power, but would also, to a considerable extent, solve at once such problems as are connected with the rapid consumption of our coal, the pollution of our rivers in manufacturing districts, the unhealthy and immoral massing of our working classes in dirty and smoky towns and cities, &c. Moreover, the space covered by the sea-side factories would in many instances be merely the almost waste border-land between sea and field.

Giessen, June 30 A. R.

Sea-Lions

It will be no doubt interesting to your readers to learn that a pair of Sea-Lions have just been added to the collection of animals in the Jardin d'Acclimatation, Paris. They are said to have been brought from the North Pacific, and are marked *Otaria stelleri*, but I think from their small size and long narrow heads that the species is more probably *Otaria ursina*, the Northern Sea Bear, whose principal habitat is the Pribylov group. They are quite young, and the female is larger than the male.

The administrative committee of the Garden has caused a large tank to be built for their reception similar to that in our Zoological Gardens, only rather larger. They seem in excellent health, and it will be interesting to see whether they breed in captivity.

They have no special attendant, so far as I could see, as the Sea-Lions at our Gardens have, and are therefore only fed at stated times. On the day of my visit the keeper was late, and the female became hungry. She gave vent to her feelings by a curious cry, a prolonged "Ah—a—a—ah," repeated at short intervals—something like the bleating of an angry sheep.

It is to be regretted that these animals were not secured for our Gardens, where the best method of managing them is so thoroughly understood, and where consequently the experiment of breeding might have been tried with a better chance of success than elsewhere. J. W. Clark

Museum of Zoology and Comparative Anatomy, Cambridge, July 11

Hereditary Affection of a Cat for a Dog

I have reared a fine mastiff. He is now three-and a-half years old. When quite a puppy he and a kitten evinced a strong liking for each other. The kitten, when able to leave her mother, fixed her residence in the dog's kennel, and never seemed happy when away from her large friend. She ate her breakfast out of the dog's bowl, and slept in his kennel with his paws around her. She used to catch mice and young rats, and carry them to him, and seemed quite pleased when he accepted friendship's offering. One morning I observed the cat preparing a bed with straw in the corner of the kennel—an ordinary wooden one, 4 feet by 2½ feet. As she was going to have kittens, I thought she intended making the kennel her nursery, and "Cato" (the dog) her head nurse. Such proved to be the case. She brought forth five kittens, and there they lay for some time. The mother frequently went away for hours, leaving the dog to look after her family. I many times stooped down to examine them, and "Cato" stood by my side quite proud of his charge. The poor

cat came to an untimely end eighteen months ago, but the only surviving kitten of the five named above is as fond of the dog as her mother was. She brings mice, young rats, and rabbits, and lays them down before "Cato," and looks beseechingly till he takes them. She constantly plays with him and gets on her hind legs to look fondly into his face, while he puts his paws round her as he used to do to her mother.

She must have *inherited* this affection from her mother, as she was too young to have imitated her mother's actions at the time of her death.

Clent, July 13

Scarcity of Birds

I SHOULD much like to know whether blackbirds and thrushes are scarce in other localities this year; because they have most unaccountably vanished from this neighbourhood, with the exception of a very few stragglers. Our cherries and strawberries are untouched. I have not observed a single blackbird or thrush in our garden or pleasure-grounds since the fruit ripened, though every other year we captured several in the cherry-nets, and shot many others.

R. M. BARRINGTON

Fassaroe Bray, co. Wicklow, July 12

OUR ASTRONOMICAL COLUMN

VARIABLE STARS.—Of the three stars to which Col. Tennant draws attention as being probably variable ("Monthly Notices R.A.S.," June 1875), B.A.C. 740 appears more especially deserving of regular observation. The B.A.C. has adopted the magnitude assigned by Groombridge, 6; other estimates are:—Hevelius, 6; Fedorenko (Lalande, 1789 November), 8; Piazzi, 8, by seven observations; Schwerd, 8½; Taylor, in 1834 or 1835, in vol. iii. of "Madras Observations," 7 (he calls the star 21 Cephei); Carrington, 8·1; the Radcliffe Catalogues, 7·5; and Durchmusterung, 8·4. With regard to the observation of Hevelius, which has been assumed to refer to this star, it may be remarked that the position given in his Catalogue for 1660, where it is No. 46 in Cepheus, does not well agree with the place of the Redhill Catalogue for B.A.C. 740, the difference of position amounting to 16′; nevertheless, it is not easy to identify the star observed by Hevelius with any other in the modern catalogues. In the cases of the stars B.A.C. 4166 and 4193, also noticed by Col. Tennant, the estimates of magnitude from the epoch of Schwerd's observations to the present time appear pretty accordant. [In comparing the magnitudes assigned in different catalogues to the naked-eye stars it is necessary to bear in mind that in Argelander's Uranometria, and in Heis and Behrmann, 6·5, 5·4, &c., apply to stars which are judged to be somewhat brighter than an average sixth or fifth magnitude, and are not to be understood decimally, as is the case in the "Durchmusterung."]

THE DOUBLE-STAR Σ 1785.—The proper motion of this star is investigated in Argelander's researches, Bonn Observations, vol. 7. He remarks: "Die Begleiter geht mit," and of this there can be no doubt, since in the interval between Struve's first measures and the last published by the Baron Dembowski, the amount of proper motion, according to Argelander's values, would be $-20''\cdot9$ in R.A. and $-2''\cdot4$ in Decl. But the relative fixity of the components, which might have been surmised from Argelander's comparison of his differences of R.A. and Decl. for 1867·34, with those deduced from Struve's angle and distance in 1830, is clearly refuted by the recent measures. Thus we have—

Struve	1830·12	Position	164°·43	Distance	3″·487
Dembowski ...	1870·81	,,	199°·60	,,	2″·431

Perhaps it is not yet practicable to decide whether this relative change is due to slight difference of proper motion or to the binary character of the star, but it is evidently one that should be regularly measured. The position for the beginning of the present year is R.A. 13h. 43m. 24s., and N.P.D. 62° 23′·6.

THE TOTAL SOLAR ECLIPSE, 1927, June 29.—We believe the Rev. S. J. Johnson, of Upton Helions, Devon, was the first who pointed out the probable totality of this eclipse for a short interval in this country. It is one of those eclipses in which the moon's augmented semidiameter exceeds that of the sun by a small quantity, even where the sun is on the meridian. The following are approximate elements:—

Conjunction in R.A. 1927, June 28, at 18h. 27m. 14s. G.M.T.

	°	′	″	
R.A.	97	6	12	
Moon's hourly motion in R.A.		37	27	
Sun's ,, ,, ...		2	36	
Moon's declination	24	4	35	N.
Sun's ,, ...	23	17	17	N.
Moon's hourly motion in Decl.		1	18	N.
Sun's ,, ,, ...		0	7	S.
Moon's horizontal parallax		57	55	
Sun's ,, ...		0	9	
Moon's true semidiameter		15	47	
Sun's ,, ...		15	44	

The sidereal time at Greenwich noon on June 29 is 6h. 26m. 17s., and the equation of time 3m. 3s. subtractive from mean time. The middle of general eclipse at 18h. 23m. 17s.

Hence the following points on the central line:—

Long. 3° 21′ W.	Lat. 54° 11′ N.	Sun's zenith distance		78°·5
,, 0 45 W.	,, 55·40	,, ,,	,,	76·3
,, 1 30 E.	,, 57 3	,, ,,	,,	74·5
,, 3 32 E.	,, 58 15 N.	,, ,,	,,	72·8

In 1° 37′ W. and 55° 12′ N. totality begins according to the above elements, June 28 at 17h. 19m. 31s. local mean time, and continues only nine seconds. It will be seen that the track of the central line in its passage over England is from Windermere, a little north of Morpeth, to the Northumberland Coast; it appears to just escape the Isle of Anglesey, but our data are not quite definitive.

MINOR PLANETS.—M. Stéphan has calculated elements of No. 146, discovered by M. Borrelly, from the Marseilles observations of June 9, 18, and 29, which give as a first approximation to the period of revolution, 1627 days; the planet has been named *Lucina*. Euphrosyne is in opposition about this time, with 57° South Declination; this body makes one of the widest excursions of any in the group, and may at times be found in Ursa Major. Daphne is the brightest of the small planets now near opposition.

SCIENCE IN GERMANY

(*From a German Correspondent.*)

IN continuation of the last report (p. 152) we make the following further communication on Götte's "History of Development." As we have already mentioned, Götte deduces the structure of the embryo from the difference in size and position of the parts resulting from the division of the ovum. He supports this theory by the following observations. In the case of all ova, first of all a difference shows itself in the vertical axis, the parts round the upper pole being smaller and generating quicker than those round the under pole. The ratio of displacement is therefore also much greater in the upper hemisphere; and as this one expands concentrically it overgrows downwards the more bulky lower hemisphere, or causes it to bulge inwards, so that from the ovum which divides into many cell-like pieces, results a beaker-shaped

formation with double sides; *these are the two original germ-layers*. The space enclosed by the inner germ-layer is the intestinal cavity; the whole formation we call *gastrula* after Haeckel. As the causes of the formation of the two germ-layers are the same for all animals consisting of more than one cell (matazoa), according to Götte's view, the form of development of the gastrula is therefore common to all, however indiscernible it may often be in the outside appearance. The cause of this is partly that the above-mentioned difference between the upper and lower hemispheres of the ovum varies in magnitude. If this difference is small, the result will be that only a moderate part of the lower hemisphere will be pressed inward, the inner germ-layer remaining simple, as for instance with the lower polypi, which on the whole consist of two layers of cells. As the energy of the inward pressure increases, a third germ-layer, the so-called middle one, is split off the stronger inner one; this third one, from being a simple intermediary layer, may develop and originate many and important organs. If in the dividing ovum only the difference referred to in the vertical axis exist, the gastrula is naturally formed equally in all directions between the two poles, so that if further transformations take place, these likewise occur equally in all directions from the intestinal cavity and its principal axis, and therefore in radiated planes or lines. Thus the difference in the first axis of the ovum, if it acts by itself, always leads to a radiated structure of body which we find with Polypi, Medusæ, Echinoidea, and their relatives. Yet the higher developed representatives of these classes already show here and there, and in unimportant points, indications of a transition to a higher type. If we suppose the two horizontal axes of the ovum to be unequal, then the formation of the gastrula must naturally be unequal likewise. The inequality, which with many of the Vermes already shows itself during the first divisions of the ovum, causes the gastrula to extend in one direction more than in any other, and thus to receive another principal axis. If at the same time the two sides precede in development the other parts, two symmetrical masses are formed, situated opposite one another (germ-streaks), and which approach each other more or less on the stomach side, and there produce certain principal organs. To this transverse divisions may be added, as in the Arthropoda; or this may not occur, as in the Mollusca. Vertebrata finally do not show the preponderance of the first formation on two opposite symmetrical sides of the ovum, but only on one, where the odd germ-streak is situated and indicates the future back. In a manner similar to that of the typical foundation of the embryo, Götte tries to deduce all other phenomena of development not from hypothetical causes of inheritance, but directly from the laws of the formation of the ovum; as, for instance, the whole development of the different organs and tissues. Any essential change in a certain animal species must then be deduced from a change in the laws of formation, which are peculiar to the ovum, *i.e.* its first cause lies in the ovum, and the live animal can never transfer newly-gained changes of form directly to the law of formation of its germs, nor thus cause its descendants to inherit them.

NEW DISCOVERY IN CONNECTION WITH THE POTATO DISEASE

THERE has been hitherto one "missing link" in our knowledge of the life-history of the potato-blight, *Peronospora infestans*. The non-sexual mode of reproduction by conidia or zoospores has long been known; but the sexual mode of reproduction has eluded observation. This link has now been supplied through the researches of Mr. Worthington Smith, who described his discovery in a paper read at the last meeting of the Scientific Committee of the Royal Horticultural Society, and published at length in the *Gardener's Chronicle* for July 10. He finds the female organs, the "resting-spores" or unfertilised "oospores," and the male organs or "antheridia," in the interior of the tissue of the tuber, stem, and leaf, when in a very advanced stage of decay; and he has actually observed the contact between the two organs in which the process of fecundation consists. In some remarks made at the meeting of the British Association last year by one of our high authorities, it was suggested that we have in the *Peronospora* an instance of the phenomenon not infrequent among fungi, known as "alternation of generations;" and that the germination of the true spores of the potato-blight must be looked for on some other plant than the potato. Mr. Worthington Smith has, however, looked nearer home, and has proved that the suggestion is not at all events verified in all cases. It is matter of congratulation that, after the lapse of a period of nearly thirty years since the publication of the first important memoir on the subject, this discovery—important alike from a scientific and a practical point of view—has fallen to one of our own countrymen, notwithstanding the foreign aid invoked by the Royal Agricultural Society in settling the still unsolved problems connected with this perplexing pest.

HISTORY OF THE PLAGIOGRAPH

I SHOULD like to add a few words to my description of the instrument called the Plagiograph * (the *g* to be pronounced soft, like *j*, as in Genesis, Plagiarist, Oxygen) in NATURE, vol. xii. p. 168, for the purpose of explaining the order of ideas in which it took its rise, and also a very beautiful extension of another recent kinematical invention to which it naturally leads the way, and which, thus generalised, I propose to term the Quadruplane.

The true view of the theory of *linkages* † is to consider every link as carrying with it an indefinitely extended plane, and to look upon the question as one of relative ‡

* It may be questioned whether a new-born child can have a history. Perhaps it might have been more correct to have used for my title, "History of the Birth of the Plagiograph," but this would have been long; moreover, the Plagiograph proves to be an unusually precocious child, having in its very cradle given birth to a greater than itself, the Quadruplane, a full-grown invention described in the sequel of the text.

† It is quite conceivable that the whole universe may constitute one great linkage, *i.e.* a system of points bound to maintain invariable distances, certain of them from certain others, and that the law of gravitation and similar physical rules for reading off natural phenomena may be the consequences of this condition of things. If the Cosmic linkage is of the kind I have called complete, then determinism is the law of Nature; but, if there be more than one degree of liberty in the system, there will be room reserved for the play of free-will. We shoud thus revert to the Aristotelian view under a somewhat wider aspect of circular (the most perfect because the simplest form of motion) being the primary (however recondite) law of cosmical dynamics. Speaking of cosmical laws brings to my mind a reflection I have made upon the new chemical theory of atomicity. Suppose it should turn out that the doctrine of *Valence* should be confirmed by experience, and that the consequent logico-mathematical theory of colligation containing the necessary laws of consecution, or if cone pleases so to say of cause and effect should plant its foot and introduce a firm basis of predictive science into chemistry, how beautiful will be the analogy between this and the physical law of inertia l which really merely affirms the fact of each atom or point of matter carrying about with it a certain number, denoting its communicative and inverse receptive faculty of motion; for in such case Valency, also affirming a numerical capacity for colligation, will be the exact analogue in chemistry to Inertia in the theory of mass motion, and might properly assume the name of chemical inertia. Social individuals differ as egregiously as Isomers in their capacity for forming multifarious attachments.

‡ I believe it is to Mr. Samuel Roberts that we are indebted for the idea of passing from mere copulated links to planes associated with the links, and for the observation that the order of the corresponding Graphs is not thereby augmented. The substitution of the more general idea of linkage for link-work, and of isolating completely the conception of relative in lieu of absolute motion, is due to the author of these lines. Take the case of a Quadruplane in which the four joints in their natural order of sequence form a contra-parallelogram. It is well known (and the fact has been applied to machinery under the name of "the parallelogram of Reulleux") that the relative motion of an opposite pair of planes may be represented by causing two curves to roll upon each other; but I add that this may be done simultaneously for both pairs of planes, giving rise to a beautiful and previously unthought-of double motion of rolling (without slip) between two ellipses for one pair and two hyperbolas for the other pair of planes. This is an immediate deduction from the conception of purely relative motion.

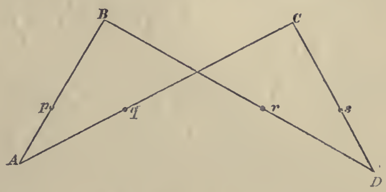
NOTE—In the description of the plagiograph, for *pointed* parallelogram, p. 168, second column, line 14, lege *jointed* parallelogram. Also a dotted line should be drawn in Fig. 1 connecting the points O and P'.

motion which may be put under this form: When a *complete* linkage (meaning thereby a combination of jointed planes capable of only a definite series of relative movements) is set in motion, *what is the curve which any point in one of these planes will describe upon any other?*

In this mode of stating the question, the lines joining the pivots round which the planes can turn correspond to the jointed rods of the common theory. Fix any one of the planes, and the linkage becomes a link-work, or, to speak with more precision, a piece-work.

The curve described by a point in one plane upon any other plane has been termed by me with general acquiescence a Graph, and to keep the correlation closely in view, I have proposed to call the describing point the Gram.* We may further understand by canonigrams describing points taken in the lines connecting the joints and their corresponding curves, canonigraphs; Grams lying outside these lines and their appurtenant Graphs may be termed Epipedograms and Epipedographs; or, if these names are found too long for use, Planigrams and Planigraphs.

Now consider more particularly the generalised form of the linkage which corresponds to three-bar motion, of which Watt's parallel motion (so-called) offers a simple instance. If we were to revert to the old notion of link-work we should say that a three-bar motion is obtained by fixing one of the sides of a jointed quadrilateral of any form; but adhering to the more general conception of the matter here set forth, we may describe it as resulting from the fixation of any one of the planes of a quadriplane, *i.e.* a system of four planes connected together by four joints. Mr. A. B. Kempe, who has brought to light magnificent additions to Peaucellier's ever memorable discovery of an exact parallel motion in a paper which I have had the pleasure of presenting to the Royal Society of London, in the course of conversation with me made the very acute and interesting remark that in an ordinary 3-bar motion, supposing the distance between the two fixed centres to be given, and the lengths of the two radial arms and the connecting rod to be also given, the order in which these three latter elements are arranged will not affect the nature of the canonigraphs described. Whichever of the three lengths is adopted as the length of the connector and the remaining two as the lengths of the radial arms, the very same system of curves will be described in all three cases so far as regards their form: every canonigram in the arrangement will have a canonigram corresponding to it in each of the other arrangements such that the corresponding curves described will be similar and similarly placed—a most remarkable, and, for the purposes of theory, an exceedingly important observation; but, as Prof. Cayley observed, when once stated, a self-evident deduction from the principle of the ordinary pantigraph.† It therefore occurred to me that a corresponding theorem ought to hold for all graphs whatever—for plagiographs just as well as for canonigraphs; and by a very simple application of the general double-algebra method of *Versors*, I found that this would be the case, the only difference being that now the corresponding graphs, instead of being similar and similarly situated, would be similar but not similarly situated; in other words, that the lines joining the centre of similitude with the corresponding points, instead of coinciding in direction, would make for each particular graph a constant angle with each other. Thus I passed from the conception of the common Pantigraph to that of the Quergraph, or Plagiograph, or Skew Pantigraph, as the new instrument described in the previous article may indifferently be called. I now come to the second part of my story, and proceed to explain the remarkable extension a theorem analogous to and naturally suggested by the



Plagiograph gives of Mr. Hart's remarkable discovery of a *cell* consisting of only four jointed rods which possesses the same property of reciprocation as Peaucellier's six-sided cell.

This cell is exhibited in the figure above. The four jointed rods A B, A C, C D, B D are equal in pairs, A B and C D being equal, also A C and B D. In fact, the figure is nothing else but a jointed parallelogram twisted out of its position of combined parallelisms, and may be termed a contra-parallelogram. When the cell is in any position whatever, imagine a geometrical line to be drawn parallel to the lines joining A and D or B and C (for these lines will obviously always remain parallel to each other), cutting the four links in the points p, q, r, s.

Now take up the cell and manipulate it in any manner you please so as to change its form, the same four points p, q, r, s will always remain in the same straight line, the distances $p\,q$ and $r\,s$ will always remain equal to one another, and the product of $p\,q$ by $p\,r$, or, which is the same thing, of $s\,r$ by $s\,q$, will never vary, so that $p\,r$ remains (so to say) a constant inverse of $p\,q$, and $s\,r$ of $s\,q$—the actual value of the constant product (called the modulus of the cell) being the difference between the squares of the unequal sides of the contra-parallelogram, multiplied by the product of the segments into which any one of the links is separated by the points p, q, r, or s, and divided by the square of such link. Now Mr. Kempe and myself—he by the free play of his vivacious geometrical imagination, I by the sure and fatal march of algebraical analysis—have arrived at the following beautiful generalisation of Mr. Hart's discovery. On A B, B D, D C, C A describe a chain of four similar triangles, the angles of which are arbitrary, but looking towards the same parts, and so placed that the equal angles in any two contiguous triangles are adjacent—call the vertices of these triangles P, Q, R, S (which will be in fact the analogues of the points p, q, r, s before mentioned): then it will be found that the figure P Q R S will be a parallelogram whose angles are invariable, and the product of whose unequal sides is constant; in a word, a

* Gram is intended to suggest the notion of a *letter* discharging the duty of a point. In inventing new verbal tools of mathemathical thought, the following are the rules which I bear in mind:—1. The word must be transferable into the common currency of the mathematical centres of Europe, France, Germany, and Italy. 2. It must enter readily into combinations and be susceptible of inflexion fore and aft. 3. It should contain some suggestion of the function of the idea intended to be conveyed. 4. It should by similarity in quality or weight of sound conjure up association with the allied ideas 5. When all these conditions are incapable of being simultaneously fulfilled, they should be observed as far as possible, and their relative importance estimated according to the order in which they are written above.

† Suppose A B, B C, C D to be three jointed rods fixed at A and D. Choose either of the fixed points, say A, and complete the parallelogram A B C B′ A, regarding C B′, B′ A as two additional jointed rods; through A draw any transversal, cutting the two indefinite straight lines A B, B B′ in P and P′ respectively; then whatever curve P describes when the system is set in motion, P′ by the principle of the common Pantigraph will describe a curve similar and similarly situated thereto, A being the centre of similitude. Now, it will be noticed that A B′ C D is a system of four jointed rods in which the lengths A B′, B′ C are the same as the lengths A B, B C in inverted order, viz., A B′ = B C, and B′ C = A B, and as we may proceed from the point D equally well as from A, it follows that all the six interchanges may be rung between the three lengths A B, B C, C D. This is the proof of Mr. Kempe's admirable theorem; but does the simplicity of the principle involved take away in any degree from the beauty of the result, or rather, is not the interest of the conclusion enhanced by the simplicity of the means by which it is arrived at? In fact, as Kant has observed, the groundwork of all mathematical proof consists in putting things together by a free act of the imagination; and the essence of Euclid is to be sought in the constructions which antecede the formal proofs. The real proof is the construction, and no one has the right to call Mr. Kempe's discovery "a truism."

parallelogram of constant area and constant obliquity.*

The modulus, or constant product of the sides, follows the same rule as in the special case, except that for the product of the segment of a link divided by the square of its entire length, must be substituted the product of the sines of the angles adjacent to any link divided by the square of the sine of the angle subtended by it.

Just as in the first case $pq.pr$ and $sr.sq$ are constant, so now PQ.PR and SR.SQ are constant; but whereas pq coincided in direction with pr and sr with sq, PQ and PR, like SR and SQ, remain inclined to each other at a constant angle; in a word, as the Plagiograph is to the Pantigraph, so is the Sylvester-Kempe Inverter or Reciprocator to Mr. Hart's.† Do not let it be supposed that this new reciprocator is to be consigned to the limbo of barren mathematical generalities—very far from it; it is very likely indeed to find a most valuable application to mechanical practice, and to subserve the purposes of that immediate "Utilitarianism" ‡ so dear to the Philistine mind; for, as by means of Mr. Hart's Quadrilateral, when one of the four named points, say p, is absolutely fixed, and one of its non-conjugate points, say r, is attached to the end of a radius so centred and of such a length that the path of r is a circle which, *geometrically* completed, would pass through p, the remaining conjugate point q will be forced to describe a straight line perpendicular to the line joining the two fixed points—so by means of our Quadruplane, when P is fixed and R made to move in the arc of a circle passing through P, the point Q may be made to describe a straight line having any *desired obliquity* to the line of centres, the amount of such obliquity depending on the magnitude of the supplemental equal angles P, Q, R, S. Thus the Plagiograph (and in the first instance Mr. Kempe's notice of the homœographic commutability of the lengths of the connecting rod and the radial bars in ordinary three-bar motion) has led by a devious path to the construction of a three-piece-work giving the most general and available solution of the problem of exact parallel motion that has been discovered or that can exist—I say the most available, for it is evident, in general, that piece-work must possess the advantage of greater firmness and steadiness from the more equal distribution of its strains over ordinary link-work.

The Peaucellier and Hart cells, duly mounted, afford the means by obvious methods of adjustment to cut straight lines at any distance from either of the fixed centres, but confined to lying perpendicular to the line of centres; whereas the Quadruplane puts it into our power with one and the same instrument affected with simple means of adjustment to make straight cuts (and, if desired, two parallel ones simultaneously) in all directions as well as at all distances in the plane of motion. So again the Plagiograph enables us to apply the principle of angular repetition (as, for instance, in making an ellipse with dimensions either fixed or varying at will, successively turn its axis to all points of the compass) to produce designs of complicated and captivating symmetry from any simple pattern or natural form, such as a flower or sprig; and as the head of a house at Oxford in the good old port-wine days was heard to complain about the electro-magnetic machine, that "he feared it would place a new weapon in the hands of the incendiary" (the power of Swing being then rampant in the land), so, but with better reason and upon the highest authority, it may be predicted that this simple invention will be found to place a new and powerful experimentative and executory implement in the hand of the engine-turner, the pattern-designer, and the architectural decorator.

J. J. SYLVESTER

Athenæum Club, and 60, Maddox Street, W.
July 5.

P.S.—I rejoice to be able to state that the Institute of France has quite recently adjudged its great mechanical prize, the "Prix Montyon," to Col. Peaucellier for his discovery of an exact parallel motion when a lieutenant in 1864. The first practical application of this discovery, made by Mr. Prim under the sanction of Dr. Percy, may be seen daily at work in the Ventilating Department of our Houses of Parliament. The workmen there, who never tire of admiring its graceful and silent action, have given it the pet name of the "Octopus," from some fancied resemblance between its backward and forward motion and that of the above-named distinguished Cephalopod. I feel a strong persuasion that when the inertia of our operative classes shall have been overcome, this application will prove to be but the signal, the first stroke of the tocsin, of an entire revolution to be wrought in every branch of construction; and that machinery is destined eventually to merge into a branch of the science of Linkage in the sense in which that word is used in the text above.

* I early noticed the analogy between M. Peaucellier's six-linked reciprocator and the primitive form of the pantigraphic proportionator formed by two parallelograms having an angle and the directions of its two containing sides in common, also therefore consisting of six links; and indeed pointed out that, starting (to fix the ideas) from a negative Peaucellier-cell (such as is in successful use in the Houses of Parliament for ventilating the brains of our representative and hereditary legislators), we have only to unfix the two interior links from the angles to which they are attached, and attach them instead to two sides of the containing lozenge, so as to be parallel to the other two sides; and we pass from a Reciprocator to the comparatively barren Proportionator. Now as a Proportionator (the Pantigraph in common use) exists with only four sides, it ought to have been inferred as fairly probable that a Reciprocator also might be discovered having only four sides, *i.e.* by analogy, the probable existence might have been inferred of a Hart cell—the contra-parallelogram first imagined by Mr. Samuel Roberts, but rediscovered and hugged with the affection of a supposed original discoverer, and warmed into new and unsuspected uses by its foster-parent Mr. Hart. I shall have no difficulty in finding a generalisation of the Peaucellier-cell standing to it in the same relation as the Quadruplane does to the Hart-cell, and similarly for the Proportionator, so that we shall have the fourfold proportion—Peaucellier-cell : Hart-cell : Quadruplane : New Peaucellier cell : : Old Pantigraph : Common Pantigraph : Plagiograph : Oblique Old Pantigraph; but, except as completing a chain of analogies, the last terms in each quatrain will probably not prove of any practical importance.

† In the case of a 3-piece motion whose fundamental linkage (*i.e.* the quadrilateral formed by the lines joining the pivots and the fixed points in their natural order of succession) is subject to the condition that either the two pairs of opposite sides or two pairs of contiguous sides are equal for each pair, the Planigraph (leaving out of account its circular portion) is the inverse of a conic. In the first case (that of the contra-parallelogram) the position of this node is seen immediately to be the opposite to the Planigram in respect to the centre of the figure in its untwisted (*i.e.* parallelogrammatic) form. In the second case, that of the so-called kite-form, it was found to be far from easy to determine its position. Even our Cayley did not quite succeed in determining it from the analytical equations, and it was reserved for M. Manheim to deduce it geometrically by a most elegant but very elaborate construction given in a paper inserted in the Proceedings of the Mathematical Society of London. By the aid of the reciprocity established by me above we pass at once from the case of the contra-parallelogram to that of the kite-form, and the problem literally solves itself as easily as a musical passage can be transposed from one key to another. It is to that profound mathematician, Mr. Samuel Roberts, that we are indebted for bringing to light these two cases of 3-bar motion, in which the general 3-bar sextic Graph breaks up into a circle, and the inside of a conic, and I have proved that no other such cases exist. Mr. Roberts's papers are inserted in the Proceedings of the London Mathematical Society, which is indebted for its existence, at least in its present form (being originally little more than a juvenile mathematical debating society among the students of University College), to the organising talents of Mr. Hirst, who has reason to be proud of his progeny. Similar societies on a precisely similar basis, and adopting the rules of its elder sister, have been subsequently founded in Paris, Warsaw, and, I believe, other capitals in Europe, and, it is safe to predict, are destined to play no unimportant part in the further evolution of our time-honoured yet ever young, ever fresh, and self-renovating science—Othello, Hamlet, and Romeo all in one. Meanwhile, in the University supposed to be peculiarly dedicated to the advance of mathematical science, a young and very promising mathematician (whose name shall not be divulged) *àpropos* of a movement kindly attempted, without my being previously consulted, to place me in a position where, in the vicinity of our central luminary, I might have been in my proper place, and helped to reflect some portion of his rays upon surrounding bodies, wrote to me lately: "You cannot imagine the bitter prejudice that prevails here against pure mathematics, &c." I freely forgive those, "the bigots of a narrow creed," who entertain such sentiments, knowing that "they know not what they do."

‡ What would our English statesmen say to the conduct of the proverbially parsimonious Prussian Government and the nineteenth century Richelieu, "dertolle Bismark" in appropriating a million and a half of marks (75,000*l.* sterling) placed at the free disposal of the modern Aristotle, Helmholtz, for constructing the bare shell alone of the new Physical Laboratory at Berlin! If such an appropriation were proposed at home, would there not run through the land a frantic shriek or muttered low of disapprobation at such a wanton waste of the public funds on mere speculative science?

CHARCOAL VACUA*

(*From a Correspondent.*)

PROF. DEWAR began his discourse by describing the different processes which have been adopted for obtaining very perfect vacua, and referred to a paper regarding this matter, read by Prof. Tait and himself before the Society last year.

By the ordinary air-pump the exhaustion can only be obtained to $\frac{1}{8}$ of an inch, *i.e.* $\frac{1}{240}$ of the ordinary pressure.

Regnault, in some of his experiments, after exhausting with the air-pump, boiled water, and when the water had evaporated, sealed the vessel, and then broke a flask inside containing sulphuric acid, and so the water vapour was absorbed.

Dr. Andrews' way is a revival of one due to Davy, viz. to fill and exhaust twice with carbonic acid after the pump exhaustion, and then by caustic potash to fix the CO_2 which is left.

Professors Tait and Dewar's method is to take advantage of the power charcoal has of condensing gases; while the exhaustion, by means of a mercury pump, is going on, the charcoal is kept heated; when the exhaustion has been carried as far as possible, the vessel is sealed, and as the charcoal cools, it condenses the very small residue of gas there may be present, and this can again be temporarily driven out by heating the charcoal. The test they have employed to gauge the perfection of their vacuum has been to see if it will allow an electric spark to pass. It is well known that at the ordinary atmospheric density it requires considerable tension for a spark to pass through air, and as the density diminishes, the spark passes more easily; but when a certain point is reached the difficulty again increases, and in a very perfect vacuum no spark passes at all. Two wires, $\frac{1}{4}$ inch apart, in one of Tait and Dewar's exhausted tubes would not allow a spark to pass, although a powerful coil was employed.

Prof. Dewar went on to say that the effect of light and heat had been tried by many experimenters, on magnets and delicately suspended bodies, and in the *Edinburgh New Philosophical Journal* for 1828 there is an interesting account of some experiments performed by Mark Watt on the same subject, with apparatus little differing in appearance from that now used by Mr. Crookes.

Recently Mr. Crookes has found some curious results which he seems to think are inexplicable. He found that the action of a beam of light on a delicately suspended glass fibre with a disc at each end was repulsion of the disc when the exhaustion was perfect, but attraction when at ordinary pressures. The discs were light bodies of pith or cork. One side of each was covered with lampblack, the other was white. The first thing to be noticed is that the blackened face is affected much sooner than the white face. Since there was attraction at one density and repulsion at another, it follows that at some intermediate density there is no action at all, and this neutral point depends among other things on the conductivity of the body and the nature of the residual gas.

It will be seen that for delicate action one essential is that the glass of the vessel be thin. The sensibility is also found to increase with the perfection of the vacuum.

The first fact ascertained is that the action follows the law of the inverse square of the distance, that which all radiation obeys. Thus, when the light was $3\frac{3}{4}$ inches from the beam, the reading was 110, zero 22, deflection 88; at $7\frac{1}{2}$, reading 48, deflection 22, or only about $\frac{1}{4}$; and when at $11\frac{1}{2}$, reading 33; and as zero changed, reading 33, deflection 9, or only about $\frac{1}{9}$.

The next experiment was this. Professor Dewar interposed between the candle and the beam a substance opaque to heat rays. The candle was placed so as to give a large deflection, and then a vessel of ordinary glass was interposed, and the deflection decreased, and on filling the vessel with water, which is almost opaque to heat rays, there was no perceptible deflection left. This shows that when the heat rays are absorbed or prevented from reaching the disc, hardly any action takes place. A layer of water $\frac{1}{4}$ of an inch thick diminishes the amount of deflection to $\frac{1}{8}$ part of the original.

Next a smoked piece of rock-salt was interposed, or a vessel filled with a substance transparent to heat but opaque to light, viz., a solution of iodine in bisulphide of carbon. The deflection was as before, large; on the empty screen being interposed a diminution followed, due to the non-transparency of the glass screen for heat. But when by means of the iodine solution the light rays were cut off there was hardly any further diminution in the deflection. This shows that the light rays may be taken away without any considerable diminution of the action.

Prof. Dewar then proceeded to show that the heating of the disc was the efficient cause of the action.

Two equal discs, one of rock-salt, the other of glass, were attached to the glass fibre. The rock-salt was inactive when the beam was thrown on it; the glass disc was active. The reason is evidently that the rock-salt is not heated, being transparent to heat, whereas the glass is opaque, absorbs the heat and is heated. Unless the shell of the receiver be thin, however, the selective action is very small, as the glass envelope absorbs much of the heat.

The back of the rock-salt disc was then coated with lampblack, and the beam sent through to the blackened side. Yet there would be attraction. The heat and light passes through the rock-salt and is absorbed by the lampblack at the surface of contact. The lampblack is heated up in consequence, but it is so bad a conductor that before this heat can be conducted through the thin coating of lampblack it is conducted through the rock-salt, heats it up, and the action is repulsion. If the lampblack were not so bad a conductor, all the lampblack would be first heated up and there would be repulsion at the other side, or apparent attraction. The subsequent action is due to the giving out heat unequally on the two sides.

The next modification was to substitute for the rock-salt clear sulphur and ordinary sulphur on the other. The peculiarity of clear sulphur is that when acted on by light it resumes the appearance of ordinary sulphur, with a disengagement of heat. A beam was thrown on this, and the effect was, as expected, attraction, the back being heated, and repulsion, there being attraction on the other side. The success of this experiment depends on the way in which the sulphur is transforming.

This suggested to the learned Professors an instrument for detecting the presence of very high violet rays. Have the transparent discs coated with white phosphorus, which is opaque to the ultra-violet rays. There would ensue a chemical action with disengagement of heat, and the result would be a motion of the discs. To show the sensitiveness of the apparatus, it may be stated that an ordinary lucifer-match held at a distance of 4 feet produced instant action, which was observed by means of a telescope. When ether was brought near there was attraction. The disc followed the ether about because there was radiation of heat from the disc. The action is clearly due to the infinitesimal heating of the discs. Reynolds suggested the action was due to the evaporation of some fluid on the surface of the discs. The recoil of the evaporating particles leaving the disc sent it back.

When the action takes place in ordinary pressures it is probably due to convection currents. The air in front of the disc is heated and ascends, there is a vacuum, and hence the disc advances. To understand the action that takes place when the exhaustion is more perfect, we must consider how much gas there is in the vessel. The capacity

* By Professors Tait and Dewar. Paper read by Prof. Dewar before the R.S. of Edinburgh on Monday, July 12.

of the vessel is about a litre or 1000 cubic centimetres. But since we know that the exhaustion has reduced the density to $\frac{1}{4000000}$ of its original, the volume occupied by the residual gas at ordinary pressures would be that of a little bubble $\frac{1}{100}$ of an inch in diameter.

Sir Wm. Thomson, T. Clerk-Maxwell, and Clausius have shown that in a gas, at ordinary pressure, the mean or average path between two collisions is about $\frac{1}{10000}$ of a millimetre. When the pressure is reduced to $\frac{1}{4000000}$ the mean will be 400 millimetres, or about a foot and a half. What takes place is this. The particles of the gas are flying about in all directions, with a velocity which depends on the temperature. When they impinge on the heated disc their velocity is increased, they go off with a greater velocity than those which go off from the colder side, and hence there is a recoil of the disc. When the gas is at all dense the particles get a very short way before they are met by another and sent back, and so the velocity gets a common velocity before any visible action takes place. When the gas is rare the particles may get a long way off before they meet others, and so the action becomes perceptible.

In case of cooling they go away with diminished velocity and a negative recoil.

The author of the paper went on to show that the total mechanical action on a square centimetre of black surface derived from the radiation of a magnesium lamp, at a distance of 150 mill., did not exceed a continuous pressure of $\frac{1}{50}$ part of a milligramme, and that the total work done did not amount to the five-millionth part of the available energy received by the movable surfaces.

ADDITION TO OUR KNOWLEDGE OF THE TERMITES *

FRITZ MÜLLER has recently published a short but interesting memoir on the larvæ of Calotermes, a genus of Termites, which he describes with his wonted care and accuracy. We cannot, of course, here follow him in detail; but, as is so often the case in the writings of this eminent naturalist, he draws our attention by his descriptions to several points of unusual interest. As occurs in some other insects, the youngest larvæ of Calotermes differ much in form from those somewhat more advanced in age. The form of the younger larvæ may be accounted for on two hypotheses. It may be an adaptation to the mode of life, or it may be the original larval form of the group. In the latter case, Herr Müller considers that it would be an extremely interesting form, because, in his opinion, Calotermes is one of the oldest, if not the oldest, of existing insect genera; since, according to Hagen, the carboniferous Termites described by Goldenburg from the cold strata belong to this group. Under the latter hypothesis, therefore, the younger larvæ of Calotermes would have, as regards insects, an interest similar to that possessed by Nauplius among Crustacea; and, according to Müller, the latter really is the case. The youngest larvæ of Calotermes live with their elder sisters, in the same localities, on the same food, and, in fact, under precisely the same conditions. These older larvæ have, in a word, completely adapted themselves to their dwelling-place and mode of life. Like most animals which burrow in earth, wood, or stone, they are cylindrical in form. Not so the youngest larvæ, which are flattened, and have the thorax laterally expanded. Their structure is, in Müller's opinion, as unsuitable as possible for animals inhabiting wood. This form is therefore probably only possessed through inheritance from far distant ancestors.

It is unnecessary to point out how great is the interest attaching to these larvæ, if Müller's view be correct; nor would I venture to express any dissent from his conclusions. But, I confess, there seems to me a difficulty in comprehending why the younger larvæ have not adapted themselves to their conditions, in like manner as their elders.

May there not possibly be some circumstances which have hitherto escaped observation, and which might render the form of these larvæ not so altogether unsuitable as Müller supposes?

I will just refer to one other point in this interesting paper. The author shows that the main, if not the whole growth of the antenna takes place in the third segment: the two basal ones and the terminal portion remaining almost unaltered. My husband, many years ago (Linn. Trans., 1863), showed this to be the case in the Ephemera (*Chloeön*), and it would be interesting to know whether the same thing occurs among other Neuroptera.

High Elms ELLEN LUBBOCK

* By Fritz Müller.

NOTES

THE Loan Exhibition of Scientific Apparatus at South Kensington, to which we have already referred (vol. xi. p. 301), will open on the 1st of April, 1876, and remain open until the end of September, after which time the objects will be returned to the owners. It will, as we have already intimated, consist of instruments and apparatus employed for research, and other scientific purposes, and for teaching. It will also include apparatus illustrative of the progress of science, and its application to the arts, as well as such as may possess special interest on account of the persons by whom, or the investigations in which, it had been employed. The precise limits are detailed under several sections in a syllabus which has been issued for the information of exhibitors. Models, drawings, or photographs will also be admissible where the originals cannot be sent. The apparatus may, in certain cases, be arranged in train as used for typical investigations; and arrangements will be made, as far as it may be found practicable, for systematically explaining and illustrating the use of the apparatus in the various sections. Forms on which to enter descriptions of objects offered for exhibition may be obtained on application to the Director of the South Kensington Museum, London, S.W. These forms should be filled up and returned as soon as possible, so that exhibitors may receive early intimation as to the admissibility of the objects they propose to send. The cost of carriage of all objects selected for exhibition will be defrayed by the Science and Art Department. It is hoped that institutions or individuals having instruments of historic interest will be good enough to lend them. The following are the various sections into which the Exhibition will be divided:—Arithmetic, Geometry, Measurement, Kinematics, Statics and Dynamics, Molecular Physics, Sound, Light, Heat, Magnetism, Electricity, Astronomy, Applied Mechanics—[as the Exhibition must be regarded as chiefly referring to education, research, and other scientific purposes, it must in this division consist principally of models, diagrams, mechanical drawings, and small machines, illustrative of the principles and progress of mechanical science, and of the application of mechanics to the arts],—Chemistry Meteorology, Geography, Geology and Mining, Mineralogy, Crystallography, and Biology.

MR. SULLIVAN on Tuesday, in the House of Commons, moved with regard to the necessity for having a Museum of Science and Art in Dublin. He, as well as the other speakers, seems to be ignorant of the fact that in addition to its educational staff and appliances, the Royal College of Science in Dublin possesses the germ of an admirable museum which formerly constituted the Museum of Irish Industry. It seems probable that what is needed is a removal of the specimens from the College to a suitable building; probably an enlargement of the Royal Dublin Society would be best, and the space thus gained in the College of cience

would be invaluable for laboratories. Few of the outside public are aware what a fine collection of mechanical apparatus the late Professor of Mathematics, Dr. Ball, made in the College, and how highly desirable it is that these should be turned to active and good use by his successor.

THE Royal Commission on Scientific Instruction and the Advancement of Science have held their final sitting and appended their signatures to the Sixth Report on Science Teaching in Public and Endowed Schools; the Seventh Report on the Universities of London, Scotland, Dublin, and the Queen's University in Ireland; and the Eighth and Final Report on the Advancement of Science and the relations of Government to that branch of study.

FOR the Paris International Geographical Exhibition an immense number of photographs have been received from the Palestine Exploration Fund, which will afford a good idea of the work done by British explorers. The Russian and Austro-Hungarian Governments have erected, each at its own expense, an elegantly fitted pavilion on the terrace *du bord de l'Eau*, where their exhibits will find ample room. M. Esler, the Danish delegate, has brought with him a complete collection of the dresses used by the natives of Greenland. All the original maps of Paris, from the celebrated tapestry carpet up to the latest published by M. Haussmann, will be exhibited by the French Government. A special section has been arranged for alimentary preparations useful for travelling purposes, and another for inventions relating to salvage.

SESSION 1875-6 of the Teachers' Classes of St. Thomas Charterhouse School of Science will commence on Sept. 25 next. A public meeting will be held on some Saturday early in October, when an address will be delivered by Dr. Carpenter. The managers of the Gilchrist Trust have made a grant for the delivery of a course of lectures, on alternate Friday evenings, during the session. The arrangements are in the hands of Dr. Carpenter, secretary to the Trust, who is in active communication with Professors Huxley and Tyndall and other eminent lecturers. The lectures will be delivered in the Foresters' Hall, Wilderness Row, near the Charterhouse Schools.

THE Committee of the French Association for the Advancement of Science, which meets at Nantes on August 19, have issued invitations and a list of some of the French men of science expected to be present. Among the subjects which will be brought before the Association are Researches on Prussic Acid, by M. Claude Bernard; an important paper by M. Pasteur on Beer; an account of the work relating to the Meridian of France, by Commandant Perrier; and a new rhinoplastic process, by Dr. Ollier. Among those expected to be present are, MM. Dumas, Claude Bernard, Pasteur, H. St. Claire Deville, De Quatrefages, Levasseur, P. Broca, E. Caventou, L. Lefort, E. Moreau, Trélau, Verneuil, and other eminent scientific Frenchmen.

AT the half-yearly general meeting of the Scottish Meteorological Society on Tuesday last two interesting papers were read; one on "The Mortality of the Large Towns of the British Islands in relation to Weather," by Mr. Buchan; and the other on "Weather and Epidemics of Scarlet Fever in London during the past thirty-five years," by Dr. Arthur Mitchell. We hope to be able to give a notice of these papers in our next number.

ON the 7th of July an extraordinary hail and thunder storm raged over a large part of France, many towns having been deluged in succession. At Geneva, where the phenomenon was more satisfactorily observed than elsewhere, it was found that the hailstones fell on a belt at first only four kilometres in breadth, but enlarging, when near the lake, to about thrice that breadth. The path of these thunderstorms will be investigated by the Meteorological Boards of the different departments, but it will take some time before they are correctly mapped. M. Dumas, at Monday's sitting of the Paris Academy, read a letter from M. Calladon, of Geneva, stating that hailstones of 300 grammes each had been collected; and a letter from M. W. de Fonvielle, describing the icicles observed by M. Duruof on his balloon in his last ascent, about ten days ago. M. Dumas directed the attention of the Academy to the importance of that observation, in order to explain how gigantic hailstones can be generated during abnormal atmospheric perturbations.

THERE is nothing particularly noteworthy in the Report presented by the Radcliffe Observer to the Board of Trustees on June 29. The work of the Observatory has been steadily pursued, interrupted only by an unusual amount of unfavourable weather. A great advance has been made in the reduction and printing of the observations during the past year.

A LIVELY interest in science seems to have been awakened in Aberdeen, by means of lectures on anatomy and physiology, delivered gratuitously by Prof. Struthers on Saturday evenings in Marischal College. They have been very largely attended by both sexes, and particularly by that portion of the community, comprising all classes, whose opportunities for instruction in scientific subjects have been necessarily restricted. A beautifully illuminated and handsomely mounted address was recently presented to Dr. Struthers by the Dean of Guild of the city on behalf of a large number of subscribers, as a mark of their appreciation of his disinterested labours. The Aberdeen School Board had been stimulated to resolve to introduce some physical science into the Grammar School. They propose to have a course of Elementary Chemistry and Elementary Physics, and also one of Botany. The Mechanics' Institution of Aberdeen, now aided by a munificent bequest from the late Dr. Neil Arnot, himself an Aberdonian, is also doing valuable work in the way of disseminating systematic knowledge in various branches of physical science.

THE Halifax Geologists' Field Club now consists of ninety members, and during the past year many papers have been read and a considerable number of excursions made. The president, Mr. J. W. Davis, in his address on May 19, gave an interesting sketch of the work done at the Settle Caves. Mr. L. C. Miall gave a lecture on the 2nd June on the Construction of Geological Maps; and on the 16th, Prof. A. H. Green lectured on the General Structure of the Central Part of Yorkshire Coal Field. The Club seems to be in a healthy condition.

WE are glad to see from the "Reports and Proceedings" for 1874 and part of 1875 of the Miners' Association of Cornwall and Devon, which carries on its work to some extent in connection with the Science and Art Department, that notwithstanding the present great depression in mining, this exceedingly useful Association has been able to continue its good work among the class for whose benefit it has been founded. The report of the lecturer, Mr. B. Kitto, F.G.S., is very satisfactory, and is followed by a number of valuable papers on various subjects connected with mining.

THE *Revue Scientifique* for July 10 contains M. J. Bertrand's valuable account of the life and work of the late M. Elie de Beaumont, recently read before the Paris Academy of Sciences.

PRINCIPAL DAWSON has sent us an interesting paper, being the Presidential Address to the Natural History Society of Montreal for 1875, entitled "Recollections of Sir Charles Lyell," containing among other things some personal reminiscences of the great geologist's visits to America.

THE "Proceedings of the American Academy of Arts and Sciences" for 1874-5 are just to hand; the following is a list of the papers contained in the volume :—Researches on the Hexatomic Compounds of Cobalt, by Wolcott Gibbs, M.D. Contributions to the Botany of North America, by Asa Gray. Graphical Integration, by Edward C. Pickering. On the Solar Motion in Space, by Truman Henry Safford. Historical Sketch of the Generic Names proposed for Butterflies: a contribution to Systematic Nomenclature, by Samuel H. Scudder. On the wide diffusion of Vanadium and its association with Phosphorus in many Rocks, by A. A. Hayes, M.D. Foci of Lenses placed obliquely, by Prof. E. C. Pickering and Dr. Chas. H. Williams. On the Effect of Heat upon the Magnetic Susceptibility of Soft Iron, by H. Amory and F. Minot. A Conspectus of the North American Hydrophyllaceæ, by Asa Gray. Revision of the Genus Ceanothus, and Descriptions of New Plants, with a Synopsis of the Western Species of Silene, by Sereno Watson. List of the Marine Algæ of the United States, with Notes of New and Imperfectly Known Species, by W. G. Farlow. On a New Induction Coil, by John Trowbridge. On the Effect of Armatures on the Magnetic State of Electro-Magnets, by B. O. Peirce and E. B. Levafour. On the Time of Demagnetisation of Soft Iron, by W. C. Hodgkins and J. H. Jennings. Light transmitted by one or more Plates of Glass, by W. W. Jacques. On the Application of Logical Analysis to Multiple Algebra, by C. S. Peirce. On the Uses and Transformations of Linear Algebra, by Benjamin Peirce. On a New Optical Constant, and on a Method of Measuring Refractive Indices without the use of Divided Instruments, by Wolcott Gibbs, M.D. Intensity of Twilight, by Charles H. Williams. Light of the Sky, by W. O. Crosby. Light absorbed by the Atmosphere of the Sun, by E. C. Pickering and D. P. Strange. Tests of a Magneto-electric Machine, by E. C. Pickering and D. P. Strange. Answer to M. Jamin's Objections to Ampère's Theory, by William W. Jacques. Melanosiderite: a New Mineral Species, from Mineral Hill, Delaware County, Pennsylvania, by Josiah P. Cooke, jun. On Two New Varieties of Vermiculites, with a Revision of the other Members of this Group, by Josiah P. Cooke, jun., and F. A. Gooch.

AT a meeting of the Council of the Royal School of Mines, held on Saturday, July 3rd, the following gentlemen received the diploma of Associate of the Royal School of Mines :—Mining and Metallurgical Divisions: Harry H. Becher, W. Frecheville, F. H. Marshall, Ambrose R. Willis. Mining Division: Archibald E. Pinching, G. Seymour, H. Lamont Young. Metallurgical Division: G. Fitz Brown, Robert Hellon, W. Foulkes Lowe, Thomas Purdie. Geological Diivsion: G. C. Frames. The following scholarships and prizes were also awarded :—Third-year Students: The De la Beche Medal and prize of books to Mr. G. Fitz Brown; the Murchison Medal and prize of books for Geology to Mr. G. Seymour. Second-year Students: H.R.H. the Duke of Cornwall's Scholarship of 30*l.* for two years to Mr. H. Louis, and the Royal Exhibition of 25*l.* to Mr. W. Hewitt. First-year Students: Two Royal Scholarships of 15*l.* each to Mr. A. N. Pearson and Mr. L. J. Whalley.

DURING the past week the Commission on Vivisection have held several meetings. The absence of Prof. Huxley is to be regretted.

IN the secret committee which was held after Monday's sitting of the Paris Academy of Sciences the claims of M. Mouchez and M. Wolf to the vacant membership in the section of Astronomy were warmly discussed. The election will probably take place next Monday. M. Mouchez is one of the most successful of the Transit observers, and M. Wolf is the sub-director of the Paris Observatory.

A SECOND specimen of a Two-horned Asiatic Rhinoceros was yesterday deposited in the Zoological Society's Gardens. It closely resembles the Hairy-eared species, and does not differ much from the Sumatran animal.

A SECOND edition has been issued of "The Unseen Universe; or, Physical Speculations on a Future State" (Macmillan and Co.)

THE Geologists' Association will make a five days' excursion into East Yorkshire, commencing on July 19.

IN connection with the calamitous floods around Toulouse, on the 25th June a singular phenomenon was observed at Clermont-sur-Lanquet. The whole of the earth on the slope of a mountain was moved bodily, a shepherd's house being transported uninjured to a distance.

WE have received a paper addressed to the Royal Society of Edinburgh by M. F. Lefort, Inspecteur-Général des Ponts et Chaussées, containing Observations relative to Mr. Edward Sang's "Remarks on the Great Logarithmic and Trigonometrical Tables calculated in the Bureau du Cadastre under the direction of Prony." Appended to the paper is Mr. Sang's reply to M. Lefort's observations.

WE have received the "Astronomical and Meteorological Observations" made during the year 1872 at the U.S. Naval Observatory.

To those who are interested in the question of the pollution of rivers, we would commend a letter to the Right Hon. G. Sclater-Booth, President of the Local Government Board, entitled "The Pollution of Rivers, by a Polluter" (Mr. E. C. Potter, of Manchester). In a very moderate and reasonable way it advances some arguments in favour of the polluter's side of the question.

THE Thirteenth Annual Report of the Birmingham Free Libraries Committee for 1874 is on the whole a satisfactory one. The aggregrate number of issues for the year is 542,887, and although this is only an increase of about 3,000 over 1873, there is a very marked increase in the issues of books to readers in the Reference Library, indicating the growing use of a higher class of works than are deposited in the Lending Library, and showing that the Free Library system is bearing fruit in raising the standard of taste and cultivation among readers. The issue of scientific works both in the Lending and Reference Libraries bears a very fair proportion to that in other departments.

WE have received a paper by Mr. W. W. Wagstaffe, of St. Thomas's Hospital, on the mechanical structure of the cancellous tissue of bone, in which the arrangement of the trabeculæ of the articular ends of the human bones are described, from sections, on the same principle as that previously adopted by Mr. F. Ward, Julius Wolff, and others.

THE additions to the Zoological Society's Gardens during the past week include a Maholi Galago (*Galago maholi*) from S. Africa, presented by Mr. C. E. Thomson; two Angulated Tortoises (*Chersina angulata*) from S. Africa, presented by Mr. L. A. Knight; a Roseate Cockatoo (*Cacatua roseicapilla*) from Australia, presented by Mr. Alfred Thompson; seven Garganey Teal (*Querquedula circia*), and a Temminck's Tragopan (*Ceriornis temmincki*) from China; two Argus Pheasants (*Argus giganteus*) from Malacca, deposited; two Giant Tortoises (*Testudo indica*) from the Aldabra Islands, purchased; a Malbrouck Monkey (*Cercopithecus cynosurus*) from W. Africa, received in exchange; a Hog Deer (*Cervus porcinus*) and five Chiloe Wigeons (*Mareca chiloensis*) born in the Gardens.

SCIENTIFIC SERIALS

Transactions of the Norfolk and Norwich Naturalists' Society, vol. ii. part i., 1874–5.—This Society has now been in existence for seven years, and at present numbers 140 members. It endeavours, we believe, faithfully to carry out one of the main objects of local societies, the study of the natural history of its district. This number of its Transactions contains the first section, Dicotyledonous, of a list of the flowering plants of Norfolk, forming the sixth instalment of the fauna and flora of the county, which the Society is publishing. Mr. John Quinton also contributes "Notes on the Meteorological Observations recorded at Norwich during 1874." A notable and excellent feature in this Society's publications is the miscellaneous notes, in which are briefly recorded new or interesting facts in the natural history of the county. There are several curious papers in this part. Mr. Amyot gives some details concerning a very old oak at Winfarthing Manor.—Mr. J. H. Gurney communicates some extracts from the notebook of the late Miss Anna Gurney of Northreps, in which she recorded noteworthy zoological occurrences in her neighbourhood, between 1820 and 1856.—A reprint of a letter by Sir J. E. Smith, from vol. vii. of the *Transactions* of the Linnean Society, gives some interesting details concerning several Norwich botanists.—Mr. T. Southwell contributes an analysis of the documents from which the "Indications of Spring," communicated to the Royal Society by Robert Marsham, F.R.S., in 1789, were compiled.—A list of 139 birds observed on the Kimberley estate, by the Earl of Kimberley.—The wild cattle at Chillingham, by Mr. C. G. Barrett, an interesting account of a visit to those rare animals.

Journal of the Franklin Institute, May.—The following are the principal papers in this number: "On the theory of the tension of belts," by Prof. L. G. Franck; the continuation of Mr. C. E. Emery's paper on "Compound and non-compound engines," and of Chief Engineer B. F. Isherwood's paper on "Experiments with different screws;" "On the mechanical equivalent of heat," the translation of a paper by M. Jules Violle. There is also a description of the Centennial Exhibition Buildings, with some excellent views, plans, and elevations.

Zeitschrift der Oesterreichischen Gesellschaft für Meteorologie, May 15.—The first paper describes a new kind of thermometer invented by Dr. Wollny, of Munich, for earth-temperature between 0·3 and 1·8 metres below the surface.—The next is the concluding part of Mr. Colding's article on winds. After explaining the effect of the rotation of the earth on great atmospheric currents, he continues as follows:—Let us consider the case of two winds, a polar and an equatorial, moving side by side in opposite directions, the polar being to the west of the other. Clearly the two will have a tendency to recede from each other, and in consequence there will be rarefaction at their neighbouring borders, producing a reaction in the two currents exactly counterbalancing the force due to rotation. Thus pressure diminishes from their outer towards their inner or neighbouring borders, where there must be a valley or depression of their surfaces. Since the magnitude of this valley depends upon the velocity of the winds, any slackening of velocity in one of them must allow it to break into the other by gravitation, and originate a hurricane revolving against the sun. It is the denser polar wind which generally breaks into the equatorial from a N.W. direction. Condensation of vapour follows, and then under certain conditions a hurricane. Now to take the other case—what will happen if the polar current flows on the east of the equatorial? The effect of the rotation of the earth will be a heaping up or condensation of air at their neighbouring borders, and the heavier current as before will invade the lighter from S.E., bringing rain. Here, however, there can be no hurricane, for gravitation acts dispersively, and the adjustment of level proceeds outwards instead of inwards. If it were possible for a hurricane to arise on the east side of the equatorial current, it would rotate "with the sun." The reason why all hurricanes rotate against the sun is now obvious. With these principles in mind, Mr. Colding thus illustrates the law of Dove: Let us imagine ourselves advancing in a westward direction out of a polar into an equatorial current. The wind turns gradually to E., then it changes to S. and S.W. as we enter the warm current; then we have it W., N.W., N., and finally N.E., in the polar current on the other side. Now at most stations where observations have been made, this direction of shift is the common one. Hence we are led to suppose that the atmosphere as a whole moves sometimes from E. to W., but more commonly from W. to E. There is good reason for this view. If the atmosphere consisted of air only, there would be no reason for an excess of eastward movement, but the equatorial current, more than the polar, carries a large quantity of vapour, and this causes an excess of pressure from W. to E. Therefore, concludes the author, Dove's law is a real law of nature.

June 1.—The chief papers in this number bear the following titles:—"The Climate of the Lower Yenesei," "Co-efficients of Temperature of Naudet's Aneroid," "An empirical demonstration of the Motive Force of the Equatorial Oceanic Current," "Quantity of Carbonic Acid Gas in Desert Air." The last paper refers to an examination of the air of the Libyan desert, by which it appears that the quantity of carbonic acid gas contained by it is about the amount found in other open places.

Reale Istituto Lombardo, Rendiconti, t. 8, fasc. iii., iv., e v.—These parts contain the following papers:—Prof. L. Maggi and G. Cantoni, on some new experiments on heterogeneity and some consequences drawn from previous series of experiments.—On the modification of the pupil observed in some cardialgies, by Dr. A. de Giovanni.—Researches on the morphogeny of alcoholic ferments, by Dr. J. Macagno.—Meteorological observations made at the Observatory of Brera, by Abate G. Capelli.—On some new parasitic fungi found by Dr. A. Cattaneo, of the Cryptogamic Laboratory, on some fruit affected by the so-called rosin disease and gangrene, by Prof. S. Garovaglio; the fungi belonged to the families of *Sporocadus sphæronema*, *Echinobotryum*, and a new kind called *Cattanea*; and the part contains some excellent illustrations of the species.—A note by Prof. C. Combroso on the causes of crime.—On the physiological effects of the *Jaborandus*, a shrub growing in the interior of some provinces of Northern Brazil, and whose leaves much resemble those of laurels, by Dr. Carlo Ambrosoli.—On the correction of temperature in a liquid into which the thermometer cannot be sufficiently immersed, by Prof. Rinaldo Ferrini.—On the centre of gravity in some homogeneous systems, by Prof. G. Bardelli.—Observations of the periodical comet of Winnecke (1819, III.), by Prof. G. V. Schiaparelli, made at the Observatory of Brera.

Freiburg Naturforschende Gesellschaft.—This Society's *Verhandlungen* (vol. vi. Parts I.–III.) contain the following more important papers:—On the action of sulphur chloride upon aniline in the presence of carbon bisulphide, by A. Claus and W. Krall.—On the action of solids upon over-saturated solutions, by F. C. Henrici.—On the occurrence and some reactions of pyrol, by W. Schlebusch.—On the decomposition of grape sugar by cupric oxide in alkaline solution, by A. Claus.—On some volcanic rocks of Java (with plates), by H. Rosenbusch.—On nitrophenylene, by A. Claus.—Microscopic mineralogical researches, by H. Fischer (second paper).—On the galvanic ignition of metal wires, by Dr. J. Müller.—A graphic representation of Ohm's law; notes on melting points; both these papers by the same.—On Diiodohydrine, by A. Claus.—Researches on the Lesser Lamprey (*Petromyzon planery*), by Dr. P. Langerhans (with plates).

THE *Gazzetta Chimica Italiana*, fasc. iv., 1875, contains the following original papers:—On the hydrate of chlorine $Cl_2 + 10H_2O$, by U. Schiff.—On the action of aniline on dichlorhydrine, by the same.—On the supposed transformation of the asparagine of vegetables into an albuminoid, by M. Mercadante.—Besides the above there is a literal translation of Prof. Clerk-Maxwell's paper on the dynamic evidence of the molecular constitution of bodies, as read at the Chemical Society in February last, and a summary of the contents of other journals.

THE "*Annali di Chimica applicata alla Medicina*" (April) contains the following papers:—On chloral-collodion, by C. Pavesi.—On the action of water upon subnitrate of bismuth, by A. Ditte.—On the morphogeny of alcoholic ferments, by Dr. J. Macagno.—On the action of nitrite of amyl upon the blood corpuscles, and on the temperature of the body during the inhalation of this substance, by W. B. Woodmann.—On the origin and propagation of disease (last paper), by Sig. Calton.—On the nature of hydrophobia, by Dr. Brunetti.

Archives des Sciences Physiques et Naturelles, No. 209, May 15.—The following are the principal original papers contained in this number:—On Anæsthetics, by Dr. J. L. Prevost. Reply to that part of M. Marc Micheli's article on the progress of botany in 1874 which concerns plant-motion, by E. Hæckel.

—On the normal spectrum of the sun, the ultra-violet part, by M. A. Cornu, with a plate.

Nachrichten von der Königl. Gesellschaft der Wissenschaften und der G. A. Universität zu Göttingen (Nos. 11–16, 1875).—From these publications we note the following papers:—Researches on the magnetism of steel rods, by Dr. Carl Fromme.—On the oscillations of a magnet under the resisting influence of a copper ball, by Franz Himstert.—On the determination of the specific conducting resistance of gas coal, by Ed. Riecke.—On hyperelliptical integrals, by L. Koenigsberger.—On the irregularities and fundamental numbers of plane curves of the third order with points, by Dr. Hermann Schubert.—On the symmetric functions of weight (XI.), by Prof. Faa de Bruno.—On the volcanic ashes of Turrialba (Costa Rica), by Heinr. O. Lang.—On the structure of German ferns, by H. Conwentz.

Göttingen Royal Society of Sciences.—Nos. 1 to 10 of this society's *Nachrichten* contain the following among other papers: On some cut stones (flints) hitherto unknown, by Fr. Wieseler.—On elastic after effects, by Fr. Kohlrausch.—On Asa Grey's group of *Diapensiaceæ*, by Dr. O. Drude.—On a new genus of Palmæ of the Arecineæ group, called *Grisebachia*, by the same and H. Wendland.—On the proof of Cauchy's theorem for complex functions, by G. Mittag-Leffler.—On the curvature of some planes, by A. Enneper.—On Rabuteau's law of the toxical effect of elements and the action of lithium, by Prof. Husemann.—On a fundamental theme of Plücker's geometry, by Dr. A. Voss.—On the ends of sensitive nerves in the skin, by Prof. F. Merkel.—On dibromobenzoic acids, by A. Burghard.—On iodosulphotoluol, by H. Glassner.—On mononitrobenzonaphtylamides, dinitrobenzonaphtylamide and their derivatives, by P. Ebell.—On *Fucus vesiculosus*, by J. Reinke.—On the action of a weak acid upon the salt of a stronger acid, by H. Hübner and H. Wiesinger.—On magnetism in steel rods, by Herr Fromme.—On the specific resistance of gas-coal, by Herr Schrader.

SOCIETIES AND ACADEMIES

London

Geological Society, June 23.—Mr. John Evans, V.P.R.S., president, in the chair.—Some observations on the Rev. O. Fisher's remarks on Mr. Mallet's theory of volcanic energy, read May 12, 1875, by Robert Mallet, F.R.S. The subject of the Rev. O. Fisher's paper has been anticipated by one from Prof. Hilgard (Geol. Univ. of Michigan) published in the *American Journal of Science* (vol. vii., June 1874). The pith of the Rev. O. Fisher's communication is to a great extent comprised in the two following sentences:—1. That "if crushing the rocks can induce fusion, then the cubes experimented upon ought to have been fused in the crushing?" 2. "If the work (of crushing) is equally distributed throughout, why should not the heat be so also? or if not, what determines the localisation?" In his reply Mr. Mallet controverts the views of the Rev. O. Fisher by bringing them into contact with acknowledged physical laws. He shows that "crushing alone of rocky masses beneath our earth's crust may be sufficient to produce fusion. He also shows that the heat developed by crushing alone cannot be equally diffused throughout the mass crushed, but must be localised, and that the circumstances of this localisation must result in producing a local temperature far greater than that due to crushing. Lastly, he shows that after the highest temperatures have been thus reached, a still further and great exaltation of temperature must arise from detrusive friction and the movements of forcible deformation of the already crushed and heated material." He therefore expresses his conviction that "there is no physical difficulty in the conception involved in his original memoir (Phil. Trans. 1873), but not there enlarged upon in detail, that the temperatures consequent upon crushing the materials of our earth's crust are sufficient locally to bring these into fusion."

On the physical conditions under which the Cambrian and Lower Silurian rocks were probably deposited over the European area, by Mr. Henry Hicks. The author indicates that the base line of the Cambrian rocks is seen everywhere in Europe to rest unconformably upon rocks supposed to be of the age of the Laurentian of Canada, and that the existence of these Pre-Cambrian rocks indicates that large continental areas existed previous to the deposition of the Cambrian rocks. The central line of the Pre-Cambrian European continent would be shown by a line drawn from S.W. to N.E. along the south coast of the English Channel, and continued through Holland and Denmark to the Baltic. Its boundaries were mountainous; they are indicated in the north by the Pre-Cambrian ridges in Pembrokeshire, in the Hebrides and Western Highlands, and by the gneissic rocks of Norway, Sweden, and Lapland. The southern line commenced to the south of Spain, passing along Southern Europe, and terminated probably in some elevated plains in Russia. Between these chains the land formed an undulating plain, sloping gradually to the south-west, its boundary in this direction being probably a line drawn from Spain to a point beyond the British Isles, now marked by the 100-fathom line. The land here facing the Atlantic Ocean would be lowest, and would be first submerged when the slow and regular depression of the Pre-Cambrian land took place. The author points out that the evidence furnished by the Cambrian and Lower Silurian deposits of Europe is in accordance with this hypothesis. In England they attain a thickness of 25,000 to 30,000 feet; in Sweden not more than 1,000 feet; and in Russia they are still thinner, and the earlier deposits seem to be wanting. In Bohemia they occupy an intermediate position as to thickness and order of deposition. The author discusses the phenomena presented by the Welsh deposits of Cambrian and Lower Silurian age, and shows that we have first conglomerates composed of pebbles of the Pre-Cambrian rocks, indicating beach conditions, then ripple-marked sandstones and shallow-water accumulations, and then, after the rather sudden occurrence of a greater depression, finer deposits containing the earliest organisms of this region, which he believes to have immigrated from the deep water of the ocean lying to the south-west. After this the depression was very gradual for a long period, and the deposits were generally formed in shallow water; then came a greater depression, marked by finer beds containing the second fauna; then a period of gradual subsidence, followed by a more decided depression of probably 1,000 feet, the deposits formed in this containing the third or "Menevian" fauna. This depression enabled the water to spread over the area between the south of Prussia and Bohemia and Norway and Sweden, there being no evidence of the presence of the first and second faunas over this area. The filling up of this depression led to the deposition of the shallow-water deposits of the Lingula-Flag group, followed by another sudden depression at the commencement of the Tremadoc epoch, which allowed the water to spread freely over the whole European area. The author next discusses the faunas of the successive epochs, and indicates that these are also in favour of his views. He indicates the probability that the animals, which are all of marine forms, migrated into the European area from some point to the south-west, probably near the equator, where he supposes the earliest types were developed. Both the lower and higher types of invertebrates appear first in the western areas; and the groups in each case as they first appear are those which biologists now recognise as being most nearly allied, and which may have developed from one common type. The lower invertebrates appear at a very much earlier period than the higher in all the areas. In the Welsh area the higher forms (the Gasteropods, Lamellibranchs, and Cephalopods) come in for the first time in Lower Tremadoc rocks; and with the exception of the presence of a Gasteropod in rather lower beds in Spain, this is the earliest evidence of these higher forms having reached the European area. At this time, however, no less than five distinct faunas of lower invertebrates had already appeared; and an enormous period, indicated by the deposition of nearly 15,000 feet of deposits, had elapsed since the first fauna had reached this area. The author points out also that a similar encroachment of the sea and migration of animals in a north-westerly direction occurred in the North American area at about the same time, the lines indicating the European and American depressions meeting in Mid-Atlantic.

On a Bone-cave in Creswell Crags, by the Rev. J. Magens Mello. In this paper the author describes some fissures containing numerous bones, situated in Creswell Crags, a ravine bounded by cliffs of Lower Permian limestone on the north-eastern borders of Derbyshire. These cliffs contain numerous fissures. The principal one described by the author penetrates about fifty yards into the rock, and has a wide opening, but is very narrow throughout the greater part of its length. It runs nearly north and south, and inclines slightly from west to east from the top downwards. The organic remains found in the first fissure belong to fourteen mammals at least, besides a bird and a fish. The mammalia are: Man, *Lepus timidus*, *Gulo luscus*, *Hyæna spelæa*, *Ursus*, sp., *Canis lupus*, *Canis vulpes*, *Canis lagopus*, *Elephas primigenius*, *Equus caballus*, *Rhinoceros ticho-*

rhinus, *Bos urus*, *Cervus megaceros*, *Cervus tarandus*, *Ovis*, sp., *Arvicola*, sp.

Notes on Haytor Iron Mine, by Clement Le Neve Foster, D.Sc.

On the formation of the Polar Ice-cap, by Mr. J. J. Murphy. The present paper is intended by the author to supplement a previous one read before the Society in 1869 (Q. J. G. S., vol. xxv. p. 350), in which he gave reasons for differing from Mr. Croll in thinking that the glacial climate was one of intense cold, and held, on the contrary, that it was one of snowy winters and cold summers, with a small range of temperature. Mr. Campbell, in a paper read before the Society in 1874, gave the following as the southernmost limits of the polar ice-cap, viz. :—In Eastern Europe, lat. 56° N. ; in Germany, 55° ; in Britain, nearly 50° ; in America, 39°. This the author considers as strong but not new evidence against the theory of ice-cap extending to low latitudes ; the extent of the ice-cap would of course not be so wide as that of the limits of glaciation, owing to the floating ice approaching nearer the equator. After commenting on Mr. Belt's remarks made during the discussion of Mr. Campbell's paper, the author states that he attributes the presence of the boulders found in the valley of the Amazon to icebergs which had drifted further than usual. The glaciation of the tropics would imply the glaciation of the whole world, which appears no more possible than that the whole world was submerged at one time. The author concludes with some remarks on a recent paper of Mr. Tylor's.

Notes on the Gasteropoda of the Guelph Formation of Canada, by Prof. H. Alleyne Nicholson, D.Sc., F.R.S.E. The author notices the occurrence of the Guelph formation as a subdivision of the Niagara series in Canada and the United States, and describes it as consisting everywhere of a cellular, yellowish, or cream-coloured dolomitic limestone of rough texture and crystalline aspect, containing innumerable cavities from which fossils of various kinds have been dissolved out. In this paper the author describes all the known Gasteropoda of the Guelph formation in Canada, including the following previously described species :—*Murchisonia Loganii* (Hall), *M. turritiformis* (Hall), *M. macrospira* (Hall), *M. bivittata* (Hall), *M. longispira* (Hall), *M. vitellia* (Billings), *M. Hercyna* (Billings), *Cyclonema ? elevata* (Hall), *Holopea guelphensis* (Billings), *H. gracia* (Billings), *Subulites ventricosus* (Hall), and *Pleurotomaria solarioides* (Hall). As new species he describes *Murchisonia Boylei*, distinguished from *M. turritiformis* (Hall) and *M. estella* (Billings) by its more rapid rate of expansion, its apparently canaliculated suture, and the existence of an angular band a little above the suture ; and *Holopea? occidentalis*, distinguished by its short but elevated spire, its large body-whorl, which becomes almost disjunct at the aperture, its circular aperture, and large umbilicus. The upper whorls are convex, but the body-whorl is obtusely angulated at about its upper fourth. Uncertain species of *Murchisonia* and *Pleurotomaria* are also indicated.

Description of a new genus of Tabulate Coral, by Mr. G. J. Hinde. The coral described by the author as constituting a new genus of Favositidæ, for which he proposes the name of *Sphærolites*, has a massive free corallum consisting of minute, polygonal, closely united corallites, growing in all directions from a central point, forming a spheroidal body, the entire surface of which is occupied by the calices of the corallites. The walls of the corallites are very delicate, with numerous pores ; the tabulæ are incomplete, formed by delicate arched lamellæ, and there are no septa. From *Chætetes* this genus is distinguished by the perforated walls and incomplete arched tabulæ ; from *Favosites* it differs in its mode of growth and its incomplete tabulæ ; and from *Michelinia* it is separated by the minuteness of its corallites, and the absence of epitheca and of septal striæ. The single species, which is named *S. Nicholsoni*, is from calcareous shale of Lower Helderberg (Ludlow) age, near Dalhousie, in New Brunswick.—(*To be continued.*)

Physical Society, June 26 (continued from p. 179).—Prof. G. C. Foster, vice-president, in the chair.—Prof. G. C. Foster called attention to the work of Prof. Everett on the Centimetre-gramme-second (C.G.S.) System of Units which will shortly be published by the Society. It is designed to facilitate the study of the quantitative relations between the different departments of physical science by the adoption of a common system of units. Prof. Foster explained that a committee of the British Association which was appointed in 1872, and of which Prof. Everett was secretary, recommended the adoption of this system, based upon the metric system, the unit of *mass* being the gramme, that of *length* the centimetre, and that of *time* the second. They recommended that the unit of force be called a *dyne*, which therefore is the force required to act upon a gramme of matter for a second to generate a velocity of a centimetre per second. The unit of work is called an *erg*, and is the amount of work done by a dyne working through the distance of a centimetre. Prof. Everett's book consists of a collection of physical data reduced to these fundamental terms, so that no other physical magnitudes enter into the expressions, and it cannot fail to prove of the greatest possible value to physicists. Prof. Foster then left the chair, which was taken by Dr. Stone.—Dr. W. M Watts communicated a paper on a new form of micrometer for use in spectroscopic analysis. In determining the positions of lines in a spectrum by the use of a micrometer eye-piece or divided arc, it is often difficult to see the cross wires distinctly without admitting extraneous light, which with faint spectra frequently cannot be done. Dr. Watts has sought to overcome this difficulty by substituting some one known line of the spectrum itself for the cross wires, and to measure the positions of unknown lines by bringing this index line successively into coincidence with them. Thus, for example, the sodium line, which is present in nearly every spectrum whether it is wanted or not, may be made to move slowly when under the spectrum, and the displacement necessary to make it coincide with the lines to be measured may be determined by the readings of a micrometer screw. To accomplish this a convex lens of about two-feet focus is placed in front of the prism of the spectroscope, between the prism and observing telescope, and is divided along a line at right-angles to the refracting edge of the prism. One half of the lens is fixed, the other half is made to slide over it by means of a micrometer screw. When the movable half of the lens is in its normal position, the only effect is to alter the focus of the telescope slightly, but when it is made to slide over the fixed half, the refraction of the prism is increased or diminished, and half of the spectrum appears to move over the other half, and the sodium line, or any other convenient line of reference can be brought into coincidence with the lines to be measured. The indications of this instrument are reduced to wave-lengths by means of a series of interpolation curves from the data obtained by observations of the solar spectrum, the coordinates of which are wave-lengths and micrometer readings. The author considers the advantages of the instrument to be (1) great precision in results ; and (2) convenience in use. In illustration of the former quality he quotes twenty readings of the point at which there is coincidence of the lenses. They are remarkably concordant, the mean being 8·34, while the two extreme readings are 8·21 and 8·41—Prof. Guthrie then read a paper on the fundamental water-waves in cylindrical vessels. He stated that many attempts had been made to connect wave-lengths with wave-amplitude, and that the most successful of these were by the brothers Weber, who allowed a column of water to fall into one end of a long trough filled with water ; and they ascertained by means of a stop-watch when the crest of the wave reached the other end. Dr. Guthrie has recently made some experiments on this subject, in which he employed a series of five vessels, varying in diameter from 5·5 to 23·5 inches. The water in each was agitated in the centre by a disc of wood, by which means the vessel was made to give what Dr. Guthrie called its "fundamental note." He counted the number of times the wave rose in the centre in a minute, and he found that amplitude has no influence upon the rate. It should also be observed that the wave effect is not the same as if the field were of infinite extent. The following are the results he obtained :—

	Diameter of vessel.	No. of pulsations per minute.
(1)	23·5 inches.	106·5
(2)	17·87 ,,	122·7
(3)	14·5 ,,	136·0
(4)	12·5 ,,	146·5
(5)	5·5 ,,	219·0

From which he deduced the curious result that a constant quantity (517·5) is obtained by multiplying the square root of the diameter by the number of pulsations. The question of depth was also carefully considered, and it was ascertained that the number of waves increases slightly with the depth.—Mr. S. C. Tisley read a paper on a new form of magneto-electric machine. After briefly describing the machines which have

hitherto been devised, he stated that the new apparatus consists essentially of an electro-magnet with shoes forming a groove, in which a Siemens' armature is made to revolve. It differs from the original machines made by Siemens and Wheatstone in the commutator, as two springs conduct the current from the cylindrical insulator, to which are attached three pieces of metal, one surrounding it for three-quarters of its circumference, the second for one quarter, and between these is a ring connected with the insulated end of the wire from the armature, and bearing two pieces of metal which are so arranged as to complete the circles of the outer pieces of metal. The armature is so constructed that a stream of water may be constantly passed through it. A small machine constructed on this principle, which without its driving gear weighs 26 lbs., is capable of raising 8 inches of platinum wire 8 inches long and ·005 inches in diameter to a red heat.—Dr. Stone then adjourned the meetings of the Society until November.

VIENNA

Imperial Academy of Sciences, Jan. 14.—The following papers were read:—On the tempera- tures arising from the mixing of sulphuric acid with water, with reference to the molecular heats and boiling points of the resulting hydrates, by Dr. L. Pfaundler.—On the occurrence of relatively high temperatures of air in the valleys of the Alps, by Prof. Kerner.—On some researches on dinitro compounds of the phenyl series, by Prof. Hlasiwetz. The author shows that phenol can easily be converted into dinitrophenol if treated with nitrous acid when dissolved in ether. At the same time mononitrophenol is formed—

$$(1)\quad C_6H_5.OH + N_2O_3 = C_6H_4N_2O + N_2O_5 + H_2O$$
$$(2)\quad 2C_6H_5.OH + N_2O_5 = 2C_6H_4.NO_2.OH + H_2O.$$

—Prof. Weiss then gave an account of his observations of the transit of Venus at Jassy. The inner contact could not be observed through clouds, but the outer one was observed at 20h. 25m. 49s·7 Jassy mean time. Prof. Weiss thinks that through the unsatisfactory state of the atmosphere this result may probably not be quite correct, and that the actual contact took place a few tenths of a second later. The longitude of the observing station was found to be 44m. 49s.·7 east of the Imperial Observatory of Vienna (probable error in this = ± 0s·1).—Prof. Oppolzer gave an account of his observations at the same place, and quoted his results in Paris mean time. In the reports of the Academy for April 1870 he had given the time for the second outer contact 18h. 45m. 25s.·7 Paris mean time; he found by observation 18h. 44m. 56s.·3 Paris mean time; difference, 29s.·4. The latitude of Jassy is given as + 47° 9′ 25″·1 (± 0″·2).

Jan. 21.—The following papers were read:—A note on the experimental determination of diamagnetism by means of its electric action of induction, by Prof. Toepler.—On the action of the muscular current upon a secondary circle of currents, and on a peculiarity of currents of induction, induced by a very weak primary current; by Prof. Brücke.—On some *Acara* and *Geophagus* species of the Amazon River, by Dr. Steindachner; in a second paper this gentleman spoke of four new Brazilian siluroids, belonging to *Oxydoras*, *Doras*, and *Rhinodoras*.

Feb. 4.—On the double refraction of quartz under pressure, by Prof. Mach.—On the latent heat of vapours, by Prof. Puschl.—On the fine structure of bones, by Prof. v. Ebner.—Detailed classification of all known Foraminifera, by A. v. Reuss.—Researches on the development of Naiades (freshwater mussels), by W. Flemming.—On the dependence of the coefficient of friction of the air upon temperature, by A. v. Obermayer.

Feb. 18.—On phenomena of flexion in the spectrum, by W. Rosicky.—On the temperatures of solidification of the hydrates of sulphuric acid and the composition of the crystals formed, by Prof. Pfaundler and E. Schnegg.

Feb. 25.—On the Tertiary strata on the north side of the Apennines from Ancona to Bologna, and on the Pliocene formations of Syracuse and Lentini, by Th. Fuchs and A. Bittner.

March 11.—On the great ice period, and on some geological theories, by Dr. A. Boué.—On anthracene and its behaviour towards iodine and mercuric oxide, by Dr. H. Hlasiwetz and Dr. O. Zeidler.

March 18.—On a consequence drawn from Biot-Savart's law, by Prof. A. Wassmuth.—On the thermoelectric behaviour of metals during melting and solidification, by A. v. Obermayer.

STOCKHOLM

Kongl. Vetenskaps Akademiens Förhandlingar, Jan. 13.—The following papers were read:—On the relation of temperature and moisture in the lowest strata of the atmosphere at daybreak, by R. Rubenson.—On the efflorescence of alum salts and their influence on vegetation, by C. E. Bergstrand.—On the conduction of heat in a cylinder, by G. Lundquist.—On the situation of moraines and terraces on the banks of many inland lakes, by A. Helland (with plate).—*Insecta Transvaalensia*, a contribution to the insect fauna of the Transvaal Republic, South Africa, by H. D. J. Wallengren.—On the low vegetation of Omberg, by P. G. E. Theorin. These papers are all in Swedish, with the exception of that by A. Helland, which is in the Danish language.

PARIS

Academy of Sciences, July 5.—M. Frémy in the chair.—The following papers were read:—A note by M. Chevreul, on the explanation of numerous phenomena which are a consequence of old age. This is the abstract of a third memoir on the subject.—On the distribution of magnetism in bundles of an infinite length composed of very thin laminæ, by M. J. Jamin.—Second note on tabular electro-magnets with multiple cores, by M. T. du Moncel.—The rain of Montpelier during twenty-three years (1852–74), from observations at the Jardin des Plantes, by M. Ch. Martins.—On the Devonian period in the Pyrenees, by M. A. Leymerie.—A letter was read from P. Secchi, accompanying the presentation of the second French edition of his work on the Sun.—Description of the group of the Pleiades and micrometric measurements of the positions of the principal stars which compose it, by M. Wolf. The author employed an object-glass of 0·31m. aperture, the positions being given to one-tenth of a minute of arc. The catalogue comprises 499 stars from the 3rd to the 14th magnitude, contained in a rectangle 135 min. long, and 90 min. broad, η Tauri occupying the centre. All the stars in the group are referable to P. Secchi's first type with regard to their spectra. The differences between the author's measurements and those of Bessel seem to point to the conclusion that the group has a proper motion towards the north-west.—Researches on carbon monosulphide, by M. Sidot. According to the author, this substance is formed by the prolonged action of light on carbon disulphide. It is described as a reddish brown powder possessing neither taste nor smell. Analyses gave numbers agreeing with the required formula CS.—On atmospheric currents, by M. J. A. Broun.—Phylloxera in the Department of Gironde, by M. Azam.—Planet 146 Lucine. Elements of the orbit calculated, by M. E. Stéphan.—On the processes of magnetisation, by M. J. M. Gaugain.—The nut from Bancoul. Chemical studies of the oleaginous fruits of tropical countries, by M. B. Corenwinder.—On the gum in wine and its influence on the determination of the glucose, by M. G. Chancel.—Chlorobrominated ethylene: isomerism of its chloride and the bromide of perchlorinated ethylene, by M. E. Bourgoin.—Influence of chalk on the distribution of the so-called "calcifuge" plants, by M. C. Contejean.—On the absorption of coloured liquids, by M. Cauvet.

THE LIFE OF LANGUAGE

The Life and Growth of Language. By William Dwight Whitney, Professor of Sanskrit and Comparative Philology in Yale College. The "International Scientific Series," vol. xvi. (London: King and Co., 1875.)

THIS is certainly a disappointing volume. When the editors of the *International Scientific Series* offered us a treatise on Language by the side of such works as Tyndall's "Forms of Water in Clouds and Rivers," Bagehot's "Physics and Politics," Bain's "Mind and Body," Spencer's "Study of Sociology," we had a right to expect something substantial, if not original. Instead of this, Prof. Whitney presents us with what is to all intents and purposes an abstract of his "Lectures on the Study of Language," delivered in 1864 in Washington and other places, lectures which in themselves contained hardly more than a popular summary of some of the results obtained by the researches of German, French, and English scholars on the origin, the development, and the classification of languages. "The old story," to let Prof. Whitney speak for himself, "is told in a new way, under changed aspects and with changed proportions, and with considerably less fullness of exposition and illustration." But why simply tell us the old story over again? Has the science of language made no progress since 1864? Has Prof. Whitney himself worked up no new materials? Has he no discovery of his own to record in his own special fields of labour? Has he brought none of the problems which, as he told us in 1864, still perplexed the students of the science of language, nearer to a solution? Or, at all events, has he not found some more felicitous illustrations than those with which he entertained his hearers ten years ago? If any one who knows the Professor's lectures, should read his new treatise on what he strangely calls the "Life and Growth of Language," we doubt not which of the two volumes he will keep on the shelves of his library, and which he will assign to the corner of ephemeral literature. Prof. Whitney has set forth his good wine at the beginning, and gives us now that which is worse. To judge from other numbers of the *International Series*, the rules imposed on the contributors do not seem to have prevented them from treating their subjects in a thorough, if not in an exhaustive way. Besides, there are in this volume several lengthy discussions as to whether the science of language should be called a physical or an historical science, whether it deserves the name of a science at all, whether a knowledge of psychology is essential to the student of language or not; discussions which, as far as we are able to judge, contain an "infinite deal of nothing," and add very little to what had already been written on these subjects.

In one respect, however, we have to congratulate Prof. Whitney most warmly on a great improvement in these his second and more sober thoughts. From beginning to end his new book is free from spite and personal invective. Neither Humboldt, nor Bopp, nor Renan, nor Schleicher, nor Bleeck, nor Steinthal, nor Goldstücker are held up to ridicule as ignorant of the A B C of grammar and logic. There is here and there a groundswell and a distant rumble, but on the whole the sea is between moderate and smooth, and we arrive at Calais with a feeling of relief and sincere thankfulness. It may be that these feelings are not shared by all readers. Man is by nature a pugnacious animal, and though in later life but few like to use the cudgels themselves, they still like to look on where there is a row. Prof. Whitney's new book therefore may seem to some people more dull than any of his former compositions; yet his true friends will rejoice that for once he has chosen the better part of valour, and in showing regard to others has shown respect for himself.

In making this laudable effort, however, Prof. Whitney seems to us to have fallen, involuntarily, no doubt, into a mistake which we hope he will forgive us for pointing out. Prof. Whitney, it is true, has not in this volume, as far as we can trust our memory, abused anybody by name. He himself takes credit for it at the end of his preface, where he says: "I have on principle avoided anything bearing the aspect of a personal controversy." But neither has he thought it necessary to add any references where he avails himself of the work done by other scholars. On this point, too, we shall quote his own words:—"And I have had to leave the text almost wholly without references, although I may here again allege the compendious cast of the work, which renders them little called for. I trust that no injustice will be found to have been done to any. The foundation of my discussion is (*sic*) the now generally accessible facts of language, which are no man's property more than another's."

This is not the first time that Prof. Whitney makes these curious excuses. In the preface to his Lectures the same or a very similar plea was put forth. We quote again his *ipsissima verba*:—"The principal facts upon which my reasonings are founded have been for some time past the commonplaces of comparative philology, and it was needless to refer for them to any particular authorities. When I have consciously taken results recently won by an individual, and to be regarded as his property, I have been careful to acknowledge it. It is, however, my duty and my pleasure here to confess my special obligations to those eminent masters in linguistic science, Professors Heinrich Steinthal, of Berlin, and August Schleicher, of Jena, whose works I have had constantly upon my table, and have freely consulted, deriving from them great instruction and enlightenment, even when I have been obliged to differ most strongly from some of their theoretical views. Upon them I have been dependent, above all, in preparing my eighth and ninth lectures; my independent acquaintance with the languages of various type throughout the world being far from sufficient to enable me to describe them at first hand. I have also borrowed here and there an illustration from the 'Lectures on the Science of Language' of Prof. Max Müller, which are especially rich in such material."

Now, what we wish to point out with reference to these repeated reservations on the part of Prof. Whitney is this. Because an author refrains from personal invective, it does not seem to us to follow that he may also dispense with giving honour where honour is due. No doubt there are a good many facts in the science of language which by this time have become public property, nay, where it would be extremely difficult to say who was their original

discoverer. That Sanskrit *asti* is the same as Latin *est*, that Sanskrit *trayas* coincided with Latin *tres*, was probably seen by every scholar who ever opened a Sanskrit grammar. In such cases it can be merely a matter of historical interest to find out who was the first lucky observer. It seems to us one of the chief merits, for instance, of Curtius's Principles of Greek Etymology, that he tells us in most cases, with the greatest conscientiousness, who were the scholars that first proposed or afterwards defended and substantiated the etymology of different words. Such references involved, no doubt, considerable trouble, and we have no right to expect in a popular work the same learned *apparatus*. But there are limits here as everywhere else, which no one can overstep with impunity. Every writer, unless his memory is growing weak, knows perfectly well what comes out of his brain, and what comes out of his pockets; what he has found out himself by dint of hard work, and what he has simply borrowed from others. A large array of footnotes and references may be in many cases a mere pedantic display of learning, but to omit all indications of sources and authorities is hardly defensible, nor can it be excused on the ground of "the compendious cast" in a book where we find, on the second page, references to two of Prof. Whitney's own writings. This is really not a matter of sentiment only, but a matter of serious import in the world of letters. Dates are easily forgotten, and of late it has happened several times that one writer has actually been blamed for having borrowed from another without acknowledgment, whereas he was the creditor and the other the debtor. This leads to awkward explanations, sometimes to angry controversies, all of which can be avoided by a frank compliance with rules long recognised in the republic of letters.

If we confine ourselves to some of the principal subjects treated in Prof. Whitney's new work, would it not have been interesting to know who first pointed out the two motive powers in the growth of language on which Prof. Whitney dwells so largely—*Phonetic Decay*, and *Dialectic Growth* or *Variation?*

Again, when an intelligible and sufficient cause was wanted for what was vaguely and metaphorically called Phonetic Decay, who was it that first ventured to suggest that there was nothing mysterious in that process, and that it could be explained in a very homely way as the result of laziness, or of economy of muscular energy?

There is one question which Prof. Whitney has treated more fully in this than in his former work, viz., the true meaning of dialect, and the relation between dialects and languages. He exhibits most ably the inevitability of dialectic variety in the very beginning of human speech, and the gradual elimination of dialectic forms in the later growth of language. Were there not others who had strongly insisted on the dialectic nature inherent in language, and had borne the brunt of the battle against numerous unbelievers?

We still remember the time when the leading philologists in Germany protested against the introduction of scientific Phonetics into Comparative Philology. If at present phonetic and physiological discussions form the introduction and groundwork to every treatise on Comparative Philology, is it not well to remember the names of those who were once ridiculed as the founders of the *Fonetik Nuz?*

It may be, as Prof. Whitney asserts, that though Germany is the home of Comparative Philology, the scholars of that country have distinguished themselves much less in that which *We* have called the Science of Language. It may be easy, as he says in another place, to note remarkable examples of men of the present generation, enjoying high distinction as comparative philologists, who, as soon as they attempt to reason on the wider truths of linguistic science, fall into incongruities and absurdities. But who were the first to conceive a Science of Language as different from Comparative Philology, though beholden to it for its most valuable materials? Who first drew the outlines of that science, collected the facts required for its illustration, and established the leading principles for its study? Prof. Whitney could have answered all these questions better than anybody else, whereas, by his reticence, he may now leave on many of his readers the impression, though no doubt very much against his own will, that the science of language had its cradle in America, and that German, English, and French scholars have added nothing to it, except "incongruities and absurdities."

After having made these reservations in favour of the founders of and former contributors to the science of language, let us now see in what Prof. Whitney's own contributions to that science consist. We shall have no difficulty in doing this, for he tells us frequently in the course of his writings what he himself has done for rescuing the science of language from the "incongruities and absurdities" of European scholars.

His first discovery is that *Language is an Institution*. No one, we believe, would feel inclined to controvert this statement. Language is an institution, and a most excellent institution.

We therefore pass on to the next discovery, which is that *Language is an Instrument*. This again is not a very startling assertion. It is well known that Plato, in trying to find out in his own Socratic method what language is, begins with the same assertion.

"*Soc.* That which has to be cut has to be cut with something?

"*Her.* Yes.

"*Soc.* And that which has to be woven or pierced has to be woven or pierced with something?

"*Her.* Certainly.

"*Soc.* And that which has to be named has to be named with something?

"*Her.* That is true.

"*Soc.* What is that with which we pierce?

"*Her.* An awl.

"*Soc.* And with which we weave?

"*Her.* A shuttle.

"*Soc.* And with which we name?

"*Her.* A name.

"*Soc.* Very good. Then a name is an instrument."

The only difference between Plato and Prof. Whitney is this, that with Plato this crude definition is but the first link in a long chain of argument, a proposition made simply in order to show its insufficiency; while Prof. Whitney seems to look upon it as free from all objections.

The third discovery which Prof. Whitney considers as peculiarly his own is, that *everybody learns his language from his parents*. While other writers on the origin of language have "aimlessly expended a surprising amount

of sapient philosophy," Prof. Whitney solves the whole question on the first page. We must again quote his own words:—

"There can be asked, respecting language, no other question of a more elementary and at the same time of a more fundamentally important character than this: How is language obtained by us? how does each speaking individual become possessed of his speech? Its true answer involves and determines well-nigh the whole of linguistic philosophy. There are probably few who would not at once reply that we learn our language; it is taught us by those among whom our lot is cast in childhood. And this obvious and common-sense answer is also, as we shall find on a more careful and considerate inquiry, the correct one."

This third discovery, too, will hardly meet with any objections. Prof. Whitney says, indeed, that two different answers are conceivable, viz., that language is inherited as a race-character, like colour, or that it is independently produced by each individual; but though we do not deny the conceivableness of such propositions, we doubt whether any being endowed with the gift of language ever made them, and whether they required "the crushing weight of facts" which Prof. Whitney brings out against them. We do not blame an author, who for argument's sake sets up what in German is called a *Strohmann*, in Sanskrit a *Púrvapaksha;* but when we read on p. 145, "There are those still who hold that words get themselves attributed to things by a kind of mysterious natural process, in which we have no part; that there are organic forces in speech itself, which by fermentation, or digestion, or crystallisation, or something of the sort, produce new material and alter old," Prof. Whitney would appear to have allowed himself to be carried away a little too far by his dramatic imagination.

To most people, however, be they scholars or philosophers, it would seem that to be told that a child learns his language from his mother, does not help them very much towards a real insight into the origin of language. We should go on from child to mother, from mother to grandmother, and so forth, but this retrogression *in infinitum* would land us exactly at the same point from which we started, viz., How did the first mother get her language? Let us hear what Prof. Whitney has to say in answer to this ever-recurring question. He tells us to look around us and to see what takes place at present. Thus, after explaining the recent discovery of a new tar colour, which by its discoverer was called *magenta*, he says:—"The word *magenta* is just as real and legitimate a part of the English language as *green*, though vastly younger and less important; and those who acquire and use the latter do so in precisely the same manner as the former, and generally with equal ignorance and unconcern as to its origin." And again, after referring to the wholly arbitrary formation of the word *gas* by Van Helmont in A.D. 1600, Prof. Whitney writes:—"We cannot follow so clearly toward or to its source the word *green*, because it is vastly older; but we do seem to arrive by inference at a connection of it with our word *grow*, and at seeing that a *green* thing was named from its being a *growing* thing; and this is a matter of no small interest as bearing on the history of the word."

Here then we have arrived at last at what Prof. Whitney would call the *pivotal* fact. The word *green* and all other words were made in the same way in which Van Helmont made the word *gas*, and the inventor of aniline colours the word *magenta*. *Green* was made from *to grow*. But, as we ventured to ask before in the case of the child, the mother, and the grandmother, would it be impertinent to ask what *to grow* was made from?

We have endeavoured to give as full an account as possible of what Prof. Whitney offers us as his own science of language, free from all the "incongruities and absurdities" of German scholars. If we have left out some facts on which he himself may lay great stress, and which he may consider as his own discoveries, we have done so from no unkind motive. He dwells, for instance, very strongly on the fact that men speak because they wish to communicate, a theory which again will hardly rouse violent opposition. However, in order to be quite just, we shall once more quote the professor's *ipsissima verba:*—

"Nor is it less plain what inaugurates the conversion and becomes the main determining element in the whole history of production of speech; it is the desire of communication. This turns the instinctive into the intentional. As itself becomes more distinct and conscious, it lifts expression of all kinds above its natural basis, and makes it an instrumentality; capable, as such, of indefinite extension and improvement. He who (as many do) leaves this force out of account, cannot but make utter shipwreck of his whole linguistic philosophy."

We should think he would. We only question whether anybody was ever ignorant of the fact that speech was meant for speaking.

On all the points hitherto mentioned, which Prof. Whitney considers as fundamental or pivotal in his Philosophy of Language, there can be little difference of opinion, nor will they excite much alarm among scholars or philosophers. There are, however, some other points of real interest and importance where we should have been extremely grateful to Prof. Whitney if he had given us not only his opinions, but the ground on which these opinions are based. It is well known that most scholars count the Mongol language as a member of the Ural-Altaic family. Prof. Whitney excludes Mongolic and Tungusic, not on linguistic, but on ethnological grounds, from that family which he calls the Scythian, a name, as Prof. Pott has already remarked, "more nebulous than Turanian." He assures us that it is not undue scepticism that leads him to limit the Scythian family for the present to its demonstrated branches, but that in this direction there has been such an excess of unscientific and wholesale grouping, the classification of ignorance, that a little even of overstrained conservatism ought to have a wholesome effect. If one considers that this reproof is administered to scholars, such as Castren, Schott, and Boller, who have devoted the whole of their lives to the study of these Turanian dialects, one cannot but look forward with the deepest interest to the publication of the results of Prof. Whitney's own studies in Mongol and Mandshu. But while we admire his conservatism on this question, we are still more struck by the boldness with which he decides questions on which the most competent scholars have hitherto spoken with great hesitation, arising not from

sentiment, whether conservative or liberal, but from a thorough appreciation of the weight of conflicting evidence. Crawfurd and others notwithstanding, Prof. Whitney assures us that the Malayan, the Polynesian, and the Melanesian languages may henceforth be safely treated as one family, as more closely related, therefore, than Mongolic and Tartaric. One more instance. The Annamese or Cochin Chinese, the Siamese, and the Burmese, whatever their differences, are all alike, we are told, in the capital point, that they are uninflected, and this cannot but be regarded as a strong indication of ultimate relationship. Provisionally, therefore, they are to be classed together as the South-eastern Asiatic, or Monosyllabic Family. All we can say at present is that we hope this is the classification of knowledge, and not of ignorance, and that we shall soon have the *pièces justificatives*, particularly with regard to the Burmese and Siamese. Some new light may also be expected from Prof. Whitney with regard to Chinese, the literature of which, we are told, goes back to 2000 B.C., whatever sceptics may say to the contrary. On all these points our expectations are raised to the highest pitch, and we hope that the professor will soon find leisure to give us not only his conclusions, but the facts on which they are founded. As we said in the beginning, we are disappointed by his present book; we are quite willing, however, to look upon it as a promise, and we have no doubt that the American scholar wil soon redeem the pledges which he has given, and thus not only relieve the science of language from "the incongruities and absurdities" of English, German, and French scholars, but enrich it by truly original American discoveries.

We may point out a few of the inaccuracies as to matters of fact which struck us in the Professor's new book.

Prof. Whitney thinks that *green* may be derived from *to grow*. Is not the root really HAR, and the transition of meaning, to be bright, to be green, to grow (grünen)? See Curtius, *s.v.* χλόη.

Agra, as a Sanskrit word corresponding to ἀγρός, is probably a misprint only. The true Sanskrit word is *Ajra*, field, with the palatal media, whereas *agra* means point.

The nasals are not formed by exit through the nose (p. 63); on the contrary the more we shut the nostrils the more nasal becomes our pronunciation. One of the earliest phoneticians, De Brosses (1709–1778), remarked very truly: "On s'exprime à contre-sens, quand on dit, *parler du nez*; c'est une espèce d'antiphrase: on parlerait du nez si on n'en avait point. S'il est bouché, si l'air n'y passe pas librement, on parlera, on chantera du nez."

The derivation of *luna* from *lucna* (p. 83) is no longer tenable, because we have to take into account the dialectic form *losna*, presupposing an original *loux-na* as in *illustris* for *inluxtris*.

On p. 215, in discussing words like *brother* and *sister*, *bull* and *cow*, *ram* and *ewe*, Prof. Whitney says: "*Man* in its distinctive sense indicates a male animal, and we have a different word, *woman*, for a female of the same kind." The choice of the illustration is not quite happy, considering that *woman*, as is well known to Prof. Whitney, is only a corruption of *wîf-man*.

M. M.

DARWIN ON CARNIVOROUS PLANTS *
II.

Insectivorous Plants. By Charles Darwin, M.A., F.R.S., &c. With Illustrations. (London: J. Murray, 1875.)

IN the Venus's Fly-trap, *Dionæa muscipula* (Fig. 5), we have a further differentiation of the organs of assimilation. The sensibility or irritability resides in three hairs—termed by Mr. Darwin "filaments"—on each half of the upper surface of the bilateral leaf; while the function of absorption appears to belong only to a number of small purplish almost sessile glands which thickly cover the whole of the upper face. These glands have also the power of secretion; but only—and here we have another variation from *Drosera*—when excited by the absorption of nitrogenous matter. The filaments are sensitive both to sudden impact and to contact with other substances, except water; the lobes of the leaf closing together, in the former case very suddenly, in the latter more slowly. If the leaf has closed in consequence of sudden impact or of the contact of non-nitrogenous matter, the two lobes remain concave, enclosing a considerable cavity; shortly re-open in perhaps twenty-four hours; and are at once again irritable. When, however, the irritating foreign substance contains soluble nitrogenous matter, the lobes of the leaf become gradually pressed closely together, and remain closed for a period of many (from nine to twenty-four) days; and when they again open, if they ever do so, are at first scarcely sensitive to renewed irritation. The mode in which (as Mr. Darwin shows) this arrangement is serviceable to the plant by securing the capture of large and permitting the escape of small insects, is highly curious, but too long to quote. The absorption of nitrogenous matter by the glands is accompanied by an aggregation of the protoplasm in the cells of the filaments, similar to that observed in *Drosera*, but this result does not follow the simple irritation of the filaments. The series of experiments described appears to prove the existence of an actual process of digestion in *Dionæa*, the closed leaf forming a temporary stomach, within which the acid secretion is poured out. The plant seems to be subject to dyspepsia, which is even fatal when it has indulged too freely in the pleasures of the table, or rather of the leaf. These observations, however, come from America, where, in its native land, its habits may possibly be more intemperate than in this country. Mr. Darwin believes the motor impulse to be transmitted in *Dionæa* as in *Drosera*, through the parenchymatous tissue of the leaf.

Aldrovanda, an aquatic, perfectly rootless genus, also belonging to the order Droseraceæ, presents phenomena similar to those of *Dionæa*, possessing sensitive hairs which cause the leaf to close, and glands which secrete a digestive fluid and afterwards absorb the digested matter. The order embraces, in addition, only three other genera, *Drosophyllum*, *Roridula*, and *Byblis*, all of which are provided with secreting glands, possessed, in all probability, of similar properties.

When the painful rumour gained circulation, not many months ago, that *Pinguicula* must be added to the list of predatory plants, it was received with even greater incredulity than the stories about *Drosera*. The facts are, however, as patent as in the plants already described.

* Continued from p. 209.

We have here no sensitive hairs, as in the Droseraceæ. The upper surface of the leaf is studded with glandular hairs of two kinds, one with longish stalks, the other nearly sessile, both of which secrete an extremely viscid fluid; and the dull irritability resides in the blade of the leaf itself,

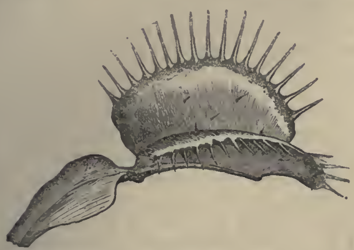

FIG. 5.—*Dionæa muscipula.* Leaf viewed laterally in its expanded state.

which becomes slowly incurved at the margins over substances that excite its sensibility (Fig. 6). This movement of the margin of the leaves (not the apex) is caused either by continued pressure from a foreign solid substance, or by the absorption of nitrogenous matter; water or a solution of sugar or gum produces no curvature; and although the latter, if sufficiently dense, excite a copious increased flow of the viscid secretion, this has no acid reaction. The increased secretion, occasioned by contact of nitrogenous solids or liquids with the glands, is, on the contrary, invariably acid, and possesses the power of rapidly dissolving and digesting insects and other nutrient substances. Some vegetable substances containing nitro-

gen, as some seeds and pollen-grains, are acted on in a similar manner, so that the butterwort is a vegetable as well as an animal feeder. The secretion appears to be again absorbed into the glands, together with the nutrient substance dissolved in it.

Until the publication of the present volume, very little was known about the habits of the singular genus *Utricularia* or Bladderwort (Fig. 7), of which several species are natives of ditches, especially of very foul water, in this country. The very finely divided leaves bear a number of minute bladders about one-tenth of an inch in length, the form

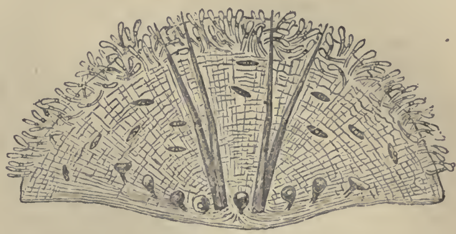

FIG. 8.—*Utricularia neglecta.* Valve of bladder; greatly enlarged.

of which, as Mr. Darwin points out, bears a very singular resemblance to that of a minute Entomostracan Crustacean. Each bladder is furnished near its mouth with two long prolongations, which Mr. Darwin calls "antennæ," branching into a number of pointed bristles. On each side of the entrance to the bladder are also a number of bristles; and the entrance is itself almost entirely closed by a movable valve (Fig. 8), which rests on a rim or collar (the "peristome" of Cohn), dipping deeply into the bladder, and can only open inwards. The surface of

Fig. 9.—*Utricularia neglecta.* One of the quadrifid processes greatly enlarged.

Fig. 10.—*Genlisea ornata.* Portion of inside of neck leading into the utricle, greatly enlarged, showing the downward pointed bristles, and small quadrifid cells or processes.

the valve is furnished with a number of glands endowed with the power of absorption, but apparently not of secretion. The whole internal surface of the bladder, with the exception of the valve, is covered with a number of minute bodies—the "quadrifid processes" (Fig. 9)—consisting of four divergent arms of unequal length and grea

flexibility; the collar itself being furnished with similar but two-armed bodies.

The use of these bladders is not merely, like the air-bladders of *Fucus*, to support the plant in the water; they are employed to capture small aquatic insects and other animals, which they do on a large scale. What it is that attracts the animals to enter the bladders is at present unknown; but, having once entered by pressing down the valve, escape is almost impossible; they sometimes get closely wedged between the valve and the collar, and thus miserably perish. But the most mysterious part of the structure of *Utricularia* is that this beautiful and complicated arrangement for capturing prey is not accompanied by any correspondingly perfect arrangement for its digestion. No secretion whatever has been observed to exude from either the glands or the quadrifid processes; pieces of meat and albumen inserted within the bladders remained absolutely unchanged for three days; and it is only when the bodies of the captured animals begin to decay that the products of decomposition are slowly absorbed by the quadrifid processes; and of even this fact the evidence can only be said to be indirect, depending on a change observed in the appearance of the protoplasmic contents of the cells of the quadrifids and of the glands on the valve and bifids on the collar, similar to that which takes place in the tentacles of *Drosera* during digestion.

The above description is taken from the rare *Utricularia neglecta*, the species first observed by Mr. Darwin; the phenomena are essentially the same in the other British forms. An epiphytic South American species, *U. montana*, bears bladders of a similar structure in all essential points, which capture a quantity of minute animals. This species is also furnished on its rhizomes with a number of small tubers, which appear to serve as reservoirs of water during the dry season. Several other species were examined, including the Brazilian *U. nelumbifolia*, found only in a very remarkable habitat, floating on the water which collects in the bottom of the leaves of a large *Tillandsia* that inhabits abundantly an arid rocky part of the Organ Mountains at an elevation of about 5,000 feet above the level of the sea. In addition to the ordinary propagation by seed, this plant is said to put out runners which are "always found directing themselves towards the nearest *Tillandsia*, when they insert their points into the water and give origin to a new plant, which in its turn sends out another shoot."

It is very curious and suggestive to compare and contrast the contrivances displayed in the two genera, *Pinguicula* and *Utricularia*, belonging to the same natural order. In the latter case we have a most elaborate and perfect contrivance for capturing insects, reminding one of what Mr. Darwin describes elsewhere as "transcending in an incomparable degree the contrivances and adaptations which the most fertile imagination of the most imaginative man could suggest;" but, when the insects are once captured, there is no contrivance for hastening the decay of their tissues, or anything comparable to animal digestion. In *Pinguicula*, on the other hand, the digestive apparatus is most complete; but there is no means whatever of capturing insects, except the very perfectness of the digestive substance itself, the extremely viscid nature of the secretion from the glands. What was the primitive form which has developed into such very diverse structures in these nearly-allied genera? Here we have a problem for the evolutionist to work out; and another for the natural selectionist—what benefit to the plant were these contrivances in their elementary rudimentary stage?—a consideration necessary to the hypothesis of their having been produced by the action of selection. There is a difficulty in conjecturing what use a digestive fluid can have been to the *Pinguicula* before it attained a degree of perfection sufficient to capture insects, or rudimentary bladders to the *Utricularia*, seeing they were not endowed with the power of digestion.

The last genus examined by Mr. Darwin belongs also to the Lentibulariaceæ, the Brazilian *Genlisea*. It is also utriculiferous; but the bladders are of a very different nature to those of *Utricularia*, being simply hollow cavities in the very long petiole or narrow part of the lamina of certain leaves specialised for this purpose. The bladders are not more than $\frac{1}{36}$th of an inch in diameter, and are surmounted by a long tube fifteen times as long and only $\frac{1}{100}$ inch in diameter, which branches at the extremity into two arms coiled in a spiral manner. Very little is known of the habits of the plant, of which only dried specimens have been examined in this country. It is probable that insects creep down the long tube into the bladders, where their remains have been found, and there perish; but whether there is any process of digestion is unknown. The escape of insects once captured is prevented, not by a valve, as in *Utricularia*, but by rows of long thin hairs pointing downwards and springing from ridges which project from the inside of the tube, as shown in fig. 10. The inside of the utricle and of the neck are furnished in addition with a number of quadrifid processes, also represented in the figure, to which the function of absorption is ascribed, and which are compared to the "quadrifids" of *Urticularia*. The drawing of these processes, more than the description, reminds us strongly of certain structures which occur in the leaves of *Drosera* and *Pinguicula*, and which we do not find referred to in the present volume; nor do we know of any description of them elsewhere. Imbedded in the tissue of the leaf of both genera—in the former case often beneath the tentacles—are a number of bodies consisting of four cells and filled with a brown matter; and we cannot but think that attention directed to these bodies may be rewarded by a further insight into the processes of digestion and absorption. They are quite distinct from the papillæ described by Mr. Darwin in the case of *Drosera*. We have seen also analogous structures represented in drawings by Dr. Hooker of either *Nepenthes* or *Sarracenia*; and similar bodies occur in the leaves of some water-plants, as *Callitriche*, to which we are not aware that any function has been assigned.

We have attempted in this notice to introduce our readers only to some of the salient points of Mr. Darwin's researches; and cannot hope to give any idea of the unwearying labour, the precision of the experiments, and the wealth of illustration, for which we must refer all interested in the subject to the volume itself. The novelty of the results arrived at does not lie in the fact of plants being found to feed on organic matter whether animal or vegetable; physiologists have long been familiar with this power in the case of parasites and saprophytes, the

former deriving their nourishment entirely from living organic matter, in some cases animal, in others vegetable; the latter from organic matter in a state of decay; but neither having the power of "assimilating," or obtaining their food-materials direct from the atmosphere and the inorganic constituents of the soil. *Saprolegnia* and *Cordiceps* are as fully entitled to the designation of carnivorous or even insectivorous plants as *Dionæa* or *Drosera*. The difference lies chiefly in the localisation of the power of absorption, which we have not generally considered to reside in the foliar organs. By far the most interesting facts brought out in this volume—and we think they are amongst the most important published for many years—are the changes from neutral to acid in the nature of the secretion poured out by the glands of Drosera on their excitement by contact with soluble nitrogenous substances; and the alleged "reflex" excitement of the tentacles of *Drosera*. It is impossible to foretell to what these discoveries will lead. We cannot but think that this volume will serve, as the previous ones from the same hand have done, to act as finger-posts to direct future observers in those lines of research which are likely to be the most fruitful and profitable.

ALFRED W. BENNETT

OUR BOOK SHELF

Progress-Report upon Geographical and Geological Explorations and Surveys west of the 100*th Meridian in* 1872, *under the direction of Brigadier-General A. A. Humphreys, Chief of Engineers, U.S. Army.* By First Lieutenant G. M. Wheeler.—Also *Topographical Atlas to illustrate Geographical Explorations west of the* 100*th Meridian.* (Washington: Government Printing Office, 1874.)

OUR readers are no doubt aware that a large area of the Western States of America is overrun by a number of expeditions intended mainly for the topographical and geological survey of that immense region. Some idea of the number and constitution of these parties will be obtained from two articles in NATURE, vol. viii. pp. 331 and 385. The "Progress-Report" for 1872 of that under charge of Lieut. G. M. Wheeler contains only brief notes of the work done by the various parties; detailed reports will, no doubt, be published eventually, and will occupy several volumes, besides atlases. The present brief report comprises notes of work done, not only in geology and topography, but also in astronomy, meteorology, natural history, ethnology, and photography. Some idea of the amount of work done may be obtained from the fact that the areas covered topographically during the summer months of 1872 exceeded 50,000 square miles lying in Utah, Nevada, and Arizona. The length of lines in the vicinity of which surveys were made is 6,127 miles, in addition to which other 2,067 miles had to be travelled for various purposes. A large portion of the present publication is occupied with reports on the numerous mining-stations which have been established in the district surveyed, as also on irrigation, agriculture, routes of communication, timber lands, and Indians; from the latter the expedition met with no interference, though of course it was accompanied by a military escort. One of the principal features of this report are the lithographic illustrations from camera-negatives of some of the magnificent cañons on the Colorado River; one of these illustrations gives a fine idea of a rain-sculptured rock at Salt-Creek Cañon, Utah.

The atlas which accompanies this Report is a magnificent work and reflects great credit on the U.S. Government and especially on the topographic section of Lieut. Wheeler's Expedition. Besides a general map, it consists of eight sectional maps in photo-lithography on the scale of one inch to eight miles, sufficiently large to give one an excellent idea of the nature of the country which has been surveyed. The maps are the results of the expeditions under Lieut. Wheeler in the years from 1869 to 1873, and embrace parts of California, Nevada, Utah, and Arizona. Every important feature is shown by characteristic and intelligible signs—mountain ranges, plateaux, cañons, bluffs, hills, craters, salt beds, sands, marshes, rivers, creeks, springs, &c., not to mention artificial features, as roads, trails, railroads, towns, &c. We understand that maps of the whole region west of the 100th meridian are to be published on this scale, and in some cases on a more extended one. It will be a magnificent work when complete, a work of which any country might be proud.

Nach den Victoriafällen des Zambesi. Von Edouard Mohr. 2 vols. (Leipzig: Hirt und Sohn, 1875.)

NOTWITHSTANDING that Herr Mohr went over ground that had been traversed previously, a considerable part of it being included in Livingstone's earlier travels, yet his book contains a great deal that is new and well worth publishing. From the time that he left Bremen in November 1868 till his departure from Africa in the beginning of 1871, the interest of his narrative never flags; the book contains frequent passages of genuine eloquence, quite free from bombast or affectation. During part of his journey, Mohr had as his companion the geologist Adolf Hübner, and their starting-point for the Victoria Falls was Durban. From this point they went almost directly to the falls, Hübner, however, leaving his companion before the Zambesi was reached, in order to visit the recently discovered South African diamond fields. Mohr, as we have indicated, tells the story of his journey and its many interesting incidents, particularly well, although, as might be expected, there were none of the dangers to be encountered which face explorers in less frequented parts of Africa. The book is full of valuable information of all kinds concerning the places touched at or visited both on the voyage out and on the journey from Durban to the Zambesi. The book must be considered as a specially valuable contribution to our knowledge of the natural history and geology, as well as to the geography of the district passed through. To the geographer the narrative will be found of very great value, as it contains a record of the carefully ascertained latitude and longitude of the principal points at which halts were made. Appended is a valuable paper by Hübner on the South African Diamond Fields. The work is illustrated by many good woodcuts and a few brilliant chromo-lithographs. There is also a small but clear map of South Africa, showing not only Mohr's route, but the routes of the principal travellers from Livingstone (1841) downwards. Altogether, the work must be considered a really valuable contribution to our knowledge of the region traversed, and seems to us well worth translating into English.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Spectroscopic *prévision* of Rain with a High Barometer

THAT the spectroscope should play a part in the prediction of weather for the common purposes of life was an early thought with many; but I have not heard of its resources being very distinctly appealed to in the late series of most memorable μετέωρα of the atmosphere which have passed over this country, setting nearly at naught most other methods of prediction.

If the instrument has been so used please to correct me. Otherwise permit me to say for myself, that being in Paris on Wednesday July 7, when the great physical and astronomical mathematician of the age, M. Leverrier, stood up in his place in the Academy of Sciences to explain how it had come about that the official predicter of the weather in the *Observatoire* had announced a fine dry period just before the destructive inundations in the South of France with all their train of frightful national calamities began,—I paid attention to the conclusion of his speech, which wound up with announcing "that all the bad symptoms had now (July 7) passed away, that the barometer was high in England, and that all the probabilities united pointed to a fine time coming."

Every day after that for a week the weather only became worse and worse, darker and wetter, in the usually gay city of Paris; and then I transferred myself to London, and was there on the 14th, 15th, and part of the 16th of July, a witness to, if possible, still worse weather, growing darker and wetter all the time. So much, then, for the failure of the ordinary methods of prediction, even in able hands; and let us be lenient to them, for who would or could have expected such deluges of rain with a high barometer, and in the month of July?

Now, however, comes an indication of where the spectroscope seems capable of saying something meteorologically useful: for in all that dark and wet weather in London a pocket spectroscope showed me from every part of the sky a broad dark band on the less refrangible side of D, and partly in the place of it. This band was so intense as to be the chief feature of the whole spectrum; and though no doubt "telluric" in its origin, was very different from the standard telluric effects seen at sunset in ordinary weather.

I feared at the time that this grandly dark spectral band might be of base artificial origin, such as an absorption effect by London smoke; and when journeying northward by rail on July 16, it was certainly charming to find that in proportion as we left London the rain ceased, the dark spectral band decreased, the clouds (amongst which, by the way, there were some remarkable counter-motions chiefly from north to south) diminished, and by the time we reached York fine weather prevailed. The ground there was dry, the rivers low, and the sky spectrum not only presented no dull bands, but the true D line was seen exquisitely fine and neat, as the thinnest imaginable spider-line in a telescope's illuminated field: so thin, fine, and clear indeed, as to offer a delight to the eye, such as none but an earnest spectroscopist can have any idea of.

Thus far, it is true, we have only had dark nebulous bands in place of fine sharp lines as *accompaniments* of rain, London rain too, with a high and steady barometer in the pleasant month of July. But mark, if you please, what follows.

The morning of the 17th of July, in Edinburgh, was glorious with pure blue sky, transparent atmosphere, delicious temperature, and light N.E. Wind. So, too, it continued all the day through, to the delight of thousands upon thousands in the streets. No smoke either was issuing from any of the factory chimneys, for there was a half-holiday or something more, and the usually working population was enjoying itself in the open air. The only clouds were a few brilliant and picturesque currents along the northern horizon, giving something like Alpine mountain snowy tops to the lovely undulations of the Scottish hills.

Simply beautiful were those bright cloud forms as an artistic feature in the general landscape; but in the spectroscope—why, good gracious! I could only say, what is the meaning of this? It was only a little pocket spectroscope, remember, without scale, and with small dispersion; but there was the D line appearing in seven times its usual strength, and with the London smoky band, too, beginning on its less refrangible side. Of the utterly abnormal intensification of D (or rather of some peculiar telluric lines so very near D as not to be separable from it in so small a spectroscope) in the light reflected from those clouds, there could not be the slightest doubt; for whenever the spectroscope was applied to a higher altitude than these clouds, there was little or nothing of the kind; only the usual Fraunhofer lines, fine and clean as generally seen in fine weather. The effect, too, was very different, both in spectrum place and distribution, from what is characteristic of a low sun; while the sun was at the time not low, no sunset colours had visibly begun, the clouds which gave the black intensification of the D line were almost absolutely white, and it was as yet only two o'clock on a fine bright July afternoon.

So I merely made comparative drawings of the spectrum given by these low white clouds, and that afforded by the general sky above them in the Polar neighbourhood, inked them in, and then waited to see what would follow.

And it was this. At 10 P.M. of that very fine day, and without any sensible falling of the high barometer, the sky clouded over completely. At 11 P.M. settled rain began. At 1.30 A.M. it was still raining, and I have reason to believe that it continued all night. It was certainly still raining in the morning of the next day, Sunday, and continued more or less all that day and all that night; while this morning, Monday, July 19, after a heavy thunderstorm, fog and heavier rain began and have proved the order of the day. All this with a barometer still nearly uninfluenced in its serene height and steadiness,* but not so the spectroscope, for, excepting the E line, all the other lines have disappeared in dull bands which occupy their places very nearly, and the London band on the less refrangible side of, and over D, is the main characteristic of all the visible spectral range.

Astronomer Royal for Scotland

OUR ASTRONOMICAL COLUMN

THE TRIPLE-STAR, SOUTH 503.—In *Astron. Nachr.*, No. 2,045, Baron Dembowski has published measures of this star made in 1873-75, which exhibit large changes in the relative situation of the components, as compared with the measures of Sir James South early in the year 1825. Thus we have for A and B:—

South.........	1825·1	Position 134°·1	Distance 39″·94
Dembowski.	1873·80	,, 120 ·3	,, 8 ·24
,,	1875·21	,, 118 ·8	,, 7 ·07

And for A and C:—

South.........	1825·1	Position 337°·3	Distance 201″·76
Dembowski.	1875·21	,, 335 ·4	,, 232 ·04

Lalande observed A and C on Jan. 23, 1798; Bessel observed all three components on March 6, 1823; and Argelander has an observation of B on Feb. 16, 1856.

On inspecting the above measures there will arise at first sight a suspicion that the change of distance between A and C and in both elements between A and B may be caused by proper motion of A nearly in the line joining A and C. To put this to the test we may take a mean between South's measures of 1825 and the angle and distance of A and C deduced from Bessel's meridian observations in 1823, and compare it with the mean of Dembowski's measures of A and C in 1875. Assuming the differences to be due to proper motion of A, we find for the annual values:—

P.M. in R.A. ... ... + 0″·389
P.M. in Decl. ... ... − 0 ·461

And, if with this proper motion we reduce Dembowski's mean of measures of A and B in 1875 to the epoch of South's observations there results:—

For 1825·1 ... ... Position 136°·5 Distance 36″·5

Considering that the P.M. adopted is only an approximation, there appears to be little doubt that the changes to which the Baron Dembowski has drawn attention in his

,, 19	29·995	58·3	57·0	N.E.

interesting note are really due to the proper motion of the principal component of this triple star.

LALANDE 23726 (CORVUS).—With reference to the query as to actual brightness of this star, which has been noted as high as a fifth magnitude by Heis (NATURE, vol. xii. p. 27), Mr. J. E. Gore writes from Umballa, under date June 8:—"I last night examined its place and found the star in question to be barely visible in an opera glass or about mag. 8." It is evidently variable to a considerable extent, and should be closely watched. Mr. Gore adds that "L. 23675-76 rated 7, $7\frac{1}{2}$ by Lalande, is now about 6m., and brighter than the stars L. 23463 (6m.) and 23446 (6m.), a little to the west;" the observations in the *Histoire Céleste*, however, do not belong to the same object, but to the two components of a double-star, which is Σ 1669, and in the Dorpat scale were both estimated 6·5 in *Mensuræ Micr.*, and 6·0 in *Positiones Mediæ*; their distance about $5\frac{1}{2}''$. Bessel also observed both components, judging them of equal brightness and of the seventh magnitude in his scale. The appearance of the object to the naked eye as a bright sixth, remarked by Mr. Gore, is thus accounted for.

HORIZONTAL REFRACTION ON VENUS.—In May 1849' near the inferior conjunction of Venus with the sun, Clausen having remarked that the crescent extended beyond a semicircle, Mädler observed it with the Dorpat telescope, with the view of approximating to the amount of horizontal refraction in the planet's atmosphere. Measures, properly so called, he found were hardly feasible, owing to the extreme faintness of the cusps and proximity of the planet to the sun, but estimations with a position-wire in the field of view were made on six days at distances varying from 3° 26′ to 7° 37′; the mean gave for the horizontal refraction, 43′·7. In 1866 Prof. C. S. Lyman, by similar observations, obtained 45′·3; he remarked: "The planet was then (for the first time, as it appears) seen as a very delicate luminous ring. The cusps of the crescent, as the planet approached the sun, had extended beyond a semicircle, until they at length coalesced and formed a perfect ring of light." Last December Prof. Lyman repeated these observations, making use of a five-feet Clarke telescope of $4\frac{2}{3}$ inches aperture, and by measures of the extent of the crescent on four days, deduces for the horizontal refraction of the atmosphere of Venus, 44′·5, a value which is also the mean of the three sets of observations. (*American Journal of Science and Arts*, January 1875). At the next inferior conjunction of Venus, she will have the following angular distances from the sun's centre, at Greenwich noon:—

1876, July 11	6° 28′	July 14	5° 8′
,, 12	5 35	,, 15	5 33
,, 13	5 5	,, 16	6 23

The formula used for finding the horizontal refraction may be thus written, putting C for the observed extent of the crescent, d for the angular distance of Venus from the sun at the time of observation, s for the sun's semi-diameter, which we may express in minutes of arc, and r for the planet's radius-vector:—

$$\text{Hor. Refr.} = \frac{1}{2}\left\{\text{Arc}\sin d \sin \tfrac{1}{2}(\text{C} - 180°) - \frac{s}{r}\right\}$$

THE SUN'S PARALLAX.—We have received Prof. Galle's *Bestimmung der Sonnen-Parallaxe aus correspondirenden Beobachtungen des Planeten Flora* (Breslau, 1875), which contains the full details of his reduction of the observations taken in both hemispheres near the opposition of the planet in 1873, when it approached the earth within about 0.87 of our mean distance from the sun. The final result for the parallax 8″.873, as already stated in this column, corresponds to 23,247 equatorial semi-diameters of the earth, or, according to Galle, 19,979,000 geographical miles of 15 to the degree of the equator.

SCIENCE IN SIAM.

WHEN the invitation of the King of Siam to observe the late total eclipse of the sun reached the Royal Society, it was hailed with delight by those who took an interest in the expedition. A few Europeans professing to know something about the country wrote letters to newspapers discouraging astronomers from accepting the invitation. Happily no notice was taken of these anonymous letters, and the result was that the members of the expedition were surprised, not only by the good reception they met with everywhere in Siam, but also by the great interest the Siamese themselves took in the eclipse and in science generally. The late king was well known for his love of astronomy, but many might suppose that this was a solitary case, and that with the death of the king science would be left unprotected in the country. A short account of our experience will show that the interest the Siamese take in science is rather on the increase than on the decrease.

On our way to the observatory, which was erected at Bangtelue, near Chulie Point, we had to stop twenty-four hours in Bangkok until the steamer which was to take us was ready. It happened that the evening of that day the "Young Siamese Society" met in the house we were staying at, and I was asked by the members to give a lecture on spectrum analysis and its application during solar eclipses. Mr. Alabaster, aided by the King's private secretary and Prince Dewan, acted as interpreter. The Siamese listened with the greatest interest, and by the questions they asked after the lecture was over showed that they fairly understood the subject. There exists a Siamese translation of a book on chemistry, and they had read up the subject in that book. H.R.H. Chowfa Maha Mala, uncle of the King, is the chief astronomer of the Siamese at the present time. He showed me the way in which he had determined the time and duration of the eclipse at Bangkok. Taking the sun and moon's apparent diameter from the *Nautical Almanac*, he determined by means of the projection of their paths and their apparent velocity the time of the different contacts. The drawing was neatly executed and, I am told, the time thus determined came very near the truth.

On the day of the eclipse several telescopes, one of which had been lent to the King by Dr. Janssen, were set up on the lawn in the front of the palace. The local time was determined by Mr. Alabaster and Capt. Bush, in order to find the exact time of the different contacts. As totality approached, the King made a speech to the members of the Royal Family, who were all assembled, telling them why solar eclipses were observed, and why large sums of money were spent for that purpose. During totality, his Majesty observed the corona and the protuberances through a telescope, carefully noting down what he saw and making a sketch of the protuberances. He had ordered one of the princes to take photographs of the corona. Two photographs were thus secured, which by no means are inferior to those taken at the Observatory of Bangtelue. The original negatives of these photographs have been sent to England as a present from the King to the Royal Society.

At our camp the Siamese also showed a great interest in the eclipse. The eagerness with which the ex-Regent looked through his telescope contrasted in a characteristic way with the quiet indifference with which his European secretary went to sleep during totality.

The King of Siam informed us that he did not profess to be an astronomer, and I was therefore rather surprised to hear afterwards that on his journey to Calcutta he had taken regular sights with the sextant, and calculated himself the position of the steamer.

But the taste of the Siamese for science is not merely confined to astronomy. Wangna, the second king, is a mineralogist. The country in which he lives gives him ample opportunity to work at his favourite subject. He

has a large mineralogical collection and a nice chemical laboratory, in which he makes his analyses.

Let us now turn from what the Siamese have done for science to what they are going to do.

The King has instructed Dr. Gowan to erect an observatory in which regular barometric and thermometric measurements are to be made. The rainfall and the tides will also form a subject of measurements. Other instruments will be added in time. As the Siamese have a great fancy for photography, we shall perhaps soon see regular photographs of the sun taken in Bangkok. Various spectroscopes and telescopes are at the present moment on their way out from England. It is also intended to build a chemical laboratory in the palace. The King's bodyguard are being instructed by Mr. Alabaster in taking surveys. At the moment I write this, they are out on a surveying expedition.

All this shows that the inhabitants of Siam have a great fancy for science, if it does not show more. Strong liking for a subject is generally accompanied with, if not caused by, the ability to deal with it and to overcome its difficulties. Let us hope that some of the Siamese will take up their favourite subject, not as amateurs merely, but with all the seriousness of a profession. Many of them visit Europe for several years. If some of these were to go through a course of science, the knowledge thus gained, added to their natural intelligence and love of science, would soon make them good observers and able experimenters.

In the meantime it will be interesting to watch the growth and development of a country in which science is the recognised and favourite study. English men of science cannot refuse their sympathy to a king who, under great difficulties, does his best to improve his country, and who readily accords to science the position which they are striving to obtain for it in their own land.

ARTHUR SCHUSTER

THE RESTING-SPORES OF THE POTATO FUNGUS

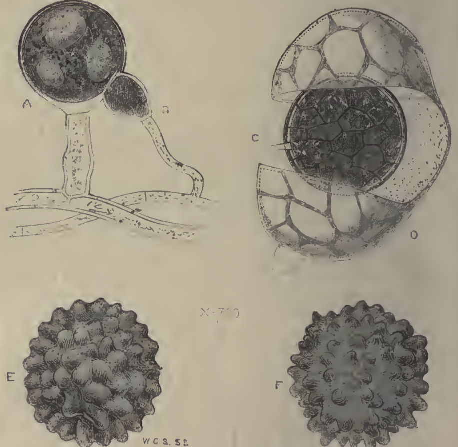
FOR some reason unknown to me (but probably owing to meteorological conditions pertaining to this season or the last) the potato fungus began its ravages this summer a month or six weeks earlier than usual. It not only appeared out of season, but it came in a different form from anything within the memory of the younger botanists of the present generation. It is considered probable that the present condition of the disease is similar with that long ago known as "the curl," a pest known a considerable time before *Peronospora infestans*, Mont., was described as European.

At the beginning of June I had potato-leaves sent to me for examination from the office of the *Journal of Horticulture*; these leaves were badly diseased, spotted and fœtid, and from certain of the stomata a few threads of the *Peronospora* were emerging; this fact, from the unusually early appearance of the fungus, I made a special note of.

On June 16 Mr. Berkeley brought leaves sent to him for examination by Mr. Andrew Murray, (which were spotted in an exactly similar manner with mine), to the meeting of the Royal Horticultural Society. At the same time Mr. Berkeley exhibited a sketch of two rather large nodulose (or reticulated) bodies found by him within these leaves, as a possible species of *Protomyces*, but since then known to be the resting-spores of *Peronospora infestans*, Mont., here illustrated.

The presence of these warted bodies in the leaves, as seen by Mr. Berkeley, led me to make a searching examination of the Chiswick plants then greatly suffering from the pest, and I at once found similar bodies very sparingly diffused amongst the tissues of the leaves, with a few branches of *Peronospora* and threads of mycelium, and two semi-transparent bodies of different sizes which were new to me. On attempting to disengage these presumed specimens of *Protomyces* from the black, hard, and corroded spots on the leaves by maceration in water, I found the continued moisture greatly excited the growth of the mycelium. After the lapse of a week the threads bore (amongst the intercellular spaces of the leaves) the semi-transparent bodies of two sizes which I had before seen and measured, and which I now refer without doubt to the oogonium and antheridium of the potato fungus. It is very uncommon to find a fungus bearing sexual and asexual fruit at the same period of growth, and in this instance the old asexual fruit was very sparingly produced. I, however, afterwards found the fungus with both forms of fruit and with ripe free resting-spores, inside the cavities of the putrid stems, and I found the ripe resting-spores and the sexual organs sometimes in conjugation within the tissues of the potato tubers when the substance was reduced by decomposition to the softness and semi-transparency of butter.

By keeping the potato-plants closely under observation from that time to this, a period of from six to seven weeks, I have seen and figured these bodies in every stage of growth, and have been able to preserve some of the best material for future careful mounting. Those who may care to know in detail how, from the slightest clue at first, the subject was worked out to its present aspect may refer to the *Gardener's Chronicle* for July 10, 17, and 24 last, and to this week's *Journal of Horticulture*.



Oogonium antheridium and mature resting spore of *Peronospora infestans*, Mont.

The antheridia, oogonia, and oospores (or resting-spores) in *Peronospora infestans*, Mont. are very similar, with the same bodies in other species of *Peronospora*, in fact when they are drawn to scale and placed side by side there is very little difference to be detected. The accompanying illustration shows the oogonium (A) and antheridium (B) in contact as taken from the tissues of the leaf. At C is shown a semi-mature resting-spore with its fecundating tube attached and its coat of cellulose accidentally pushed aside by maceration in water, as taken from a putrid potato-stem. At E is illustrated the perfectly mature resting-spore, free from its coat of cellulose taken from a tuber in the last stage of decomposition. At F is shown the resting-spore of *Peronospora arenariæ*, Berk, drawn to exactly the same scale to show similarity in size and conformation. The figures in the cut are uniformly enlarged seven hundred diameters, and the mature oospore or resting-spore measures on the average ·00142 inch in in length, and ·00114 inch in breadth.

WORTHINGTON G. SMITH

*ELECTRICAL RESISTANCE THERMOMETER AND PYROMETER**

THIS paper consists of three parts. The first treats of the experiments made by Dr. Siemens, with a view of determining the law of the variation of electrical resistance in metallic conductors, with variation of temperature, through a greater range than had been before attempted. The second describes certain instruments, by whose use this law is applied to the measurement of temperature. The third treats of a simple method of measuring electrical resistance by means of the differential voltameter.

Our author first refers to the previous experiments made by Arnsted, by his brother, Dr. Werner Siemens, and by Dr. Matthiessen, and to the law deduced by Clausius, "that the electrical resistances of metals are directly proportional to their absolute temperatures." The maximum range of these experiments was 100° C. Dr. Siemens's experiments were made upon copper, iron, steel, silver, aluminium, and platinum; the last of these has received the most attention at his hands, as, having the highest melting point, it is the most valuable from a practical point of view.

The method employed in one series of experiments was to wind metal wire upon pipe-clay cylinders, having helical grooves to prevent contact between the convolutions of the wire, and to place these, together with three delicate thermometers, in a copper vessel enclosed in a larger one containing linseed oil, and having hollow sides packed with sand to diminish sudden variation of temperature. The bath was gradually heated by means of Bunsen's burners to 340° C., or close to the boiling point of mercury, and the readings were made with a Wheatstone's bridge and delicate galvanometer. A second series of experiments was made in a heated air vessel having a metallic screen to prevent irregular losses of heat by radiation or by atmospheric currents, the other conditions being similar to those in the first series. The results obtained were found to accord generally with those of Matthiessen and the other observers within the limits of their experiments, but pointed to a different law of increase beyond those limits. The formula hitherto known as Matthiessen's is—

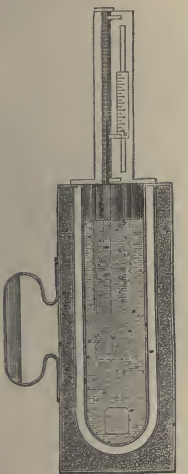


FIG. 1.

$$R_t = \frac{R_v}{1 - \cdot 0037647\, t + \cdot 00000834\, t^2}$$

and was the mean of the results obtained on various metals. This formula is shown to give discordant results at the higher temperatures, as the calculated resistance at 300° C. is 1·61 nearly of what it is at 0° C., whilst at 2000° C. it is ·0373, showing clearly that the formula is reliable only between very narrow limits.

We quote the author as to the law of resistance which he proposes: "Now, if we apply the mechanical laws of work and velocity to the vibratory motions of a body which represent its free heat, we should define this heat as directly proportional to the square of the velocity with which the atoms, or may be the molecules, vibrate.

"We may further assume that the resistance which a metallic body offers to the passage of an electrical impulse from atom to atom, or from molecule to molecule, is directly proportional to the velocity of the vibrations which represent its heat. In combining these two assumptions, it follows that the resistance of a metallic body increases in the direct ratio of the square root of the free heat communicated to it. Algebraically, if r represent the resistance of a metallic conductor at the temperature T, reckoning from the absolute zero, and α, an experimental coefficient of increase peculiar to the particular metal under consideration, we should have the expression—

$$r = \alpha\, T^{\frac{1}{2}}.$$

This purely parabolic expression would make no allowance for the probable increase of resistance, due to the increasing distance between adjoining particles with increase of heat, which would depend upon the coefficient of expansion, and may be expressed by β T, which would have to be added to the former expression. To these factors a third would have to be added expressing an ultimate constant resistance of the material itself at the absolute zero, and which I call γ. The total resistance of a conductor at any temperature, T, would, therefore, be expressed by the formula—

$$r = \alpha T^{\frac{1}{2}} + \beta T + \gamma.$$

Diagrams are given in which this hypothetical law is graphically represented, and in which its results are compared with those obtained by the experiments already cited, and by this means the following formulæ are arrived at for the different metals named:—

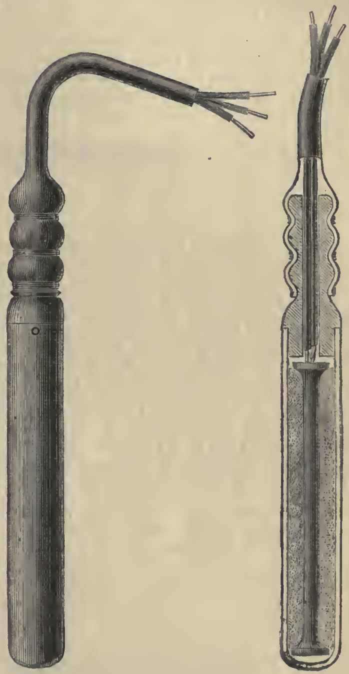

FIG. 2.

For platinum	$r = \cdot 0021448\ T^{\frac{1}{2}}$	$+ \cdot 0024187\ T$	$+ \cdot 30425$
	$r = \cdot 039369\ T^{\frac{1}{2}}$	$+ \cdot 00216407\ T$	$- \cdot 24127$
	$r = \cdot 092183\ T^{\frac{1}{2}}$	$+ \cdot 00007781\ T$	$- \cdot 50196$
For copper ...	$r = \cdot 026577\ T^{\frac{1}{2}}$	$+ \cdot 0031443\ T$	$- \cdot 29751$
,, iron ...	$r = \cdot 072545\ T^{\frac{1}{2}}$	$+ \cdot 0038133\ T$	$- 1 \cdot 23971$
,, aluminium	$r = \cdot 05951436\ T^{\frac{1}{2}}$	$+ \cdot 00284603\ T$	$- \cdot 76492$
,, silver ...	$r = \cdot 0060907\ T^{\frac{1}{2}}$	$+ \cdot 0035538\ T$	$- \cdot 07456$

Dr. Siemens, however, has not been satisfied with limiting his experiments to temperatures within the boiling point of mercury, but compared the law he had deduced with experimental results at higher temperatures obtained by the use of the metal ball pyrometer shown in Fig 1. Its principal parts are a metal ball, whose heat capacity equals one-fiftieth of that of an imperial pint of water, a copper vessel containing a pint of water, and a thermometer having a fixed and sliding scale with divisions of equal size, but each division in the latter being equivalent to fifty in the former. The zero of the sliding scale is fixed to coincide with the position of the mercury level in the thermometer. The ball, having been heated, is dropped into the water, whose temperature is the sum of those indicated on the fixed and sliding scales. By the use of this instrument, whose readings were compared with those of the mercury thermometer

* Abstract of a Paper read at the Society of Telegraph Engineers by C. William Siemens, D.C.L., F.R.S., &c.

up to the boiling-point of the latter metal, results at higher temperatures were obtained. The first part concludes with several pages of tabulated results of experiments, which results are laid down in a sheet of diagrams.

In the second part, Dr. Siemens describes the instruments he has designed for the measurement of temperature by electrical resistance, having first referred to the coils of silk-covered copper wire, by which he was enabled to detect a dangerous rise of temperature in the Malta and Alexandria Telegraph cable, coiled in ship's hold, and saved that cable from being destroyed. The simplest of these arrangements is shown in Fig. 2, and is employed for the measurement of temperature not exceeding the boiling point of water. Insulated wire is wound round a cylindrical piece of wood and is enclosed in a metal casing: one end is joined to a thicker insulated wire, and the other to a similar one soldered to it; this is called the thermometric resistance coil or thermometer coil. The thermometrical comparison coil is formed of an exactly similar wire, and has an equal resistance with the other. The wire is wound upon a metal tube, and is enclosed in a protecting capsule of metal, in the open end of which is fitted a vulcanite stopper through which are passed the leading wires attached to the coil. This is placed in a movable tube having a flanged bottom and containing a mercury thermometer; the tube is immersed in a cylindrical vessel of water, wherein it is moved up and down, the flange agitating and thus equalising the temperature of the water. The thermometer coil, which may be at a distance from the place of observation, is connected with the comparison coil through a pair of equal resistances and a galvanometer. When electrical equilibrium is obtained, by adding hot or cold water to the vessel containing the comparison coil until the galvanometer needle is at the zero of its scale, it is evident that $\frac{A}{B} = \frac{T + l}{T' + l'}$ A and B representing the equal resistances, l and l' the equal resistances of the leading wires, and T T′ those of the thermometer and resistance coils, or T = T′, and the temperature of the water in which the comparison coil is placed will be that of the distant station.

In measuring deep-sea temperatures the coil must be so protected as to be perfectly insulated at the greatest depths, and the

FIG. 3.

wire so coiled as to be effected by slight variations of temperature in its vicinity. The necessary instrument is shown in the sketch Fig. 3, which represents an insulated wire coiled on a metal tube; one end of the wire is soldered to the tube, the other to a copper wire insulated with gutta percha, and carried through a hole to the interior: over each end of the tube is drawn a piece of vulcanised india-rubber pipe, and over the whole a larger piece of india-rubber tubing, which, after being padded outside with hemp yarn, is lashed tightly with a stout binding wire. The gutta-percha covered wire is placed between the india-rubber pipes b and c, its end being soldered to one of the leading wires, the other leading wire being soldered to the brass tube. The whole is carried at the end of the sounding line, which contains the leading wires. These coils are tested under hydrostatic pressure, and accurate readings are obtained to a tenth of a degree Fahrenheit.

The only difficulty that has hitherto arisen in the employment of this instrument has been the obtaining of skilled observers to note with accuracy the indications of the galvanoscope on board ship.

The next instrument described is the electrical pyrometer, the coil of which is made of platinum wire, wound on a hard baked pipe-clay cylinder in which a doubled threaded helical groove is formed, and which is shown in Fig. 4.

At each end of the spiral portion B B, it is provided with a ring-formed projecting rim c and c', the purpose of which is to keep the cylinder in place when it is inserted in the outer metal case, and to prevent the possibility of contact between the case and the platinum wire. Through the lower ring c' are the small holes $b\ b'$, and through the upper portion two others, $a\ a$. The use of the upper holes $a\ a'$ is for passing the ends of the platinum wires through, before connecting them with the leading wires. From these two holes downwards platinum wires are coiled in parallel convolutions round the cylinder to the bottom, where they are passed separately through the holes $b\,b'$. Here they are twisted, and by preference fused together by means of an oxyhydrogen blow-pipe. At this end also the effective length and resistance of the platinum wire can be adjusted, which is accomplished by forming a return loop of the wire, and providing a connecting screw-link of platinum, L, by which any portion of the loop can be cut off from the electrical circuit.

The pipe-clay cylinder is inserted in the lower portion of the

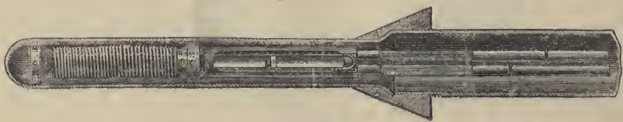

FIG. 4.

protecting case seen in Fig. 6. This part of the case is made of iron or platinum, and is fitted into the long tube, which is of wrought iron, and serves as a handle. When the lower end of the casing is of iron, there is a platinum shield to protect the coil on the pipe-clay cylinder. The purpose of the platinum casing is to shield the resistance wire against hot gases, and against accident. At the points A A, Fig. 4, the thick platinum wires are joined to copper connections, over which pieces of ordinary clay tobacco-pipe are drawn, and which terminate in binding screws fitted to a block of pipe-clay, closing the end of the tube. A third binding screw is provided, which is likewise connected with one of the two copper connecting wires, and which serves to eliminate disturbing resistances in the leading wires. The pipe-clay cylinder is, when cold, highly insulating; its conducting power increases with heat, but not to an extent to produce error, as the variation is inappreciable until a white heat is reached, but in measuring temperatures above a white heat, the indications of the instrument are slightly below the true value. In measuring temperatures with this instrument the differential voltameter is employed, a wide range of resistances being obtained; this instrument forms the subject of the third part o this paper, to which we now refer. The theory of differential mea surement and the instrument employed are thus described by Dr. Siemens:—

Faraday established the law that the decomposition of water in a voltameter in an unit of time is a measure of the intensity of the current employed; or, that

$$I = \frac{V}{t};$$

—I being the intensity, V the volume, and t the time.

According to Ohm's general law, the intensity, I, is directly governed by the electro-motive force, E, and, inversely, by the resistance, R, of the electric circuit, or, it is

$$I = \frac{E}{R}.$$

Combining the two laws we have

$$V = \frac{E}{R}t,$$

which formula would enable us to determine any unknown

resistance, R, by the amount of decomposition effected in a voltameter in a given time, and by means of a battery of known electromotive force.

Practically, however, such a result would be of no value, because the electromotive force of the battery is counteracted by the polarisation, or electrical tension, set up between the electrodes of the voltameter, which depends upon the temperature and concentration of the acid employed, and upon the condition of the platinum surfaces composing the electrodes. The resistance to be measured would, moreover, comprise that of the voltameter, which would have to be frequently ascertained by other methods, and the notation of time would involve considerable inconvenience and error. For these reasons the voltameter has been hitherto discarded as a measuring instrument, but the disturbing causes just enumerated may be eliminated by combining two similar voltameters in one instrument, which I propose calling a "differential voltameter," and which is represented in the accompanying drawing.

It consists of two similar narrow glass tubes, A and B, of about 2·5 millimetres in diameter, fixed vertically to a wooden frame, F, with a scale behind them divided into millimetres or other divisions. The lower ends of these tubes are enlarged to about 6 millimetres in diameter, and each of them is fitted with a wooden stopper saturated with paraffin and pierced by two

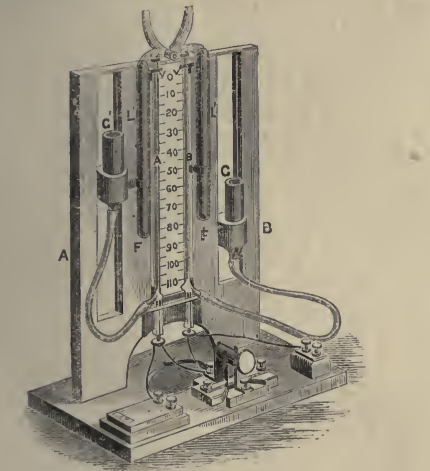

FIG. 5.

platinum wires, the tapered ends of which reach about 25 millimetres above the level of the stopper. These form voltametric electrodes.

From the enlarged portion of each of the two voltameter tubes a branch tube emanates, connected, by means of an india-rubber tube, the one to the moveable glass reservoir G, and the other to G′, Fig. 5. These reservoirs are supported in sliding frames by means of friction springs, and may be raised and lowered at pleasure. The upper extremities of the voltameter tubes are cut smooth and left open, but weighted levers, L and L′, are provided, with india-rubber pads, which usually press down upon the open ends, closing them, but admitting of their being raised, with a view of allowing the interior of the tubes to be in open communication with the atmosphere. Having filled the adjustible reservoirs with dilute sulphuric acid on opening the ends of the voltameter tubes, the liquid in each tube will rise to a level with that of its respective reservoir, and the latter is moved to its highest position before allowing the ends of the tubes to be closed by the weighted and padded levers.

The ends of the platinum wire forming the electrodes may be platinised with advantage, in order to increase the active surface for the generation of the gases.

Fig. 6 represents the connections of the voltameter with the pyrometer. One electrode of each voltameter is connected with a common binding-screw, which latter may be united, at will, to either pole of the battery, whilst the remaining two electrodes are, at the same moment, connected with the other pole of the same battery; the one through the constant resistance-coil, X, and the other through the unknown resistance, X′. This unknown resistance, X′, is represented to be a pyrometer-coil.

By turning the commutator seen at Fig. 5 either in a right or left-hand direction from its central or neutral position (in which position the contact-springs on either side rest on ebonite), the current from the battery flows through the two circuits, causing decomposition in the voltameters; and the gases generated upon the electrodes accumulate in the upper portions of the graduated tubes. By turning the commutator half round every few seconds, the current from the battery is reversed, which prevents polarisation of the electrodes, as already stated.

The relative volumes, v and v', of the gases accumulated in an arbitrary space of time within each tube must be inversely proportional to the resistances, R and R', of the branch circuits, because—

$$v : v' = \frac{E}{R} t : \frac{E}{R'} t,$$

and, therefore,

$$v : v' = R' : R.$$

The resistances R and R' are composed, the one of the resistance

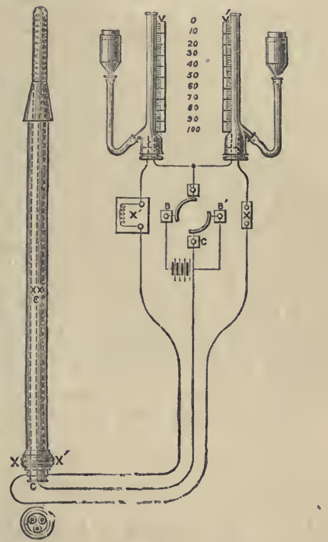

FIG.

C, plus the resistance of the voltameter A, and the other of the unknown resistance X, plus the resistance of the voltameter B. But the instrument has been so adjusted that the resistances of the two voltameters are alike, being made as small as possible, or equal to about 1 mercury unit, to which has to be added the resistances of the leading wires, which are also made equal to each other, and to about half a unit; these resistances may therefore both of them be expressed by γ.

We have, then—

$$v' : v = C + \gamma : X + \gamma,$$

or—

$$X = \frac{v}{v'}(C + \gamma) - \gamma \quad . \quad . \quad . \quad . \quad . \quad (1)$$

which is a convenient formula for calculating the unknown resistance from the known quantities C and γ, and the observed proportion of v and v'.

The constant of the instrument (γ) is easily determined, from time to time, by substituting a known resistance for X, and observing the volumes, v and v', after the current has been acting during an arbitrary space of time, when in the above formula, γ, has to be separated as the unknown quantity, giving it the form—

$$\gamma = \pm \frac{v' X - v C}{v - v'} \quad . \quad . \quad . \quad . \quad . \quad (2)$$

The condition of equality between the internal resistances of

both voltameters is ascertained by inserting equal known resistances in both branch circuits, when

$$v = v'$$

should be the result. Failing this, the balance is generally re-established by reversing the poles of the battery, the reason being that hydrogen electrodes are liable to accumulate metallic or other deposit upon their surfaces, which is effectually removed by oxygen.

When the instrument is to be worked between wide ranges of temperature, it is requisite that C should be variable, and nearly equal to X, and that γ should be very small compared with X.

By equating the values of the equations

$$X = \frac{v}{v'}(C+\gamma) - \gamma = r = {\cdot}039369\, t^{\frac{1}{2}} + {\cdot}00216407\, t - {\cdot}24127,$$

C and γ in the instruments constructed being equal to 17 and 2 units, we arrive at

$$t^{\circ}\text{Cent.} = \left\{ (877{\cdot}975 \times \frac{v}{v'} + 101{\cdot}80877)^{\frac{1}{2}} - 9{\cdot}0960553 \right\}^2 - 274^{\circ},$$

from which a table has been prepared to be used with the pyrometer.

The precautions which have to be taken to insure reliable results in using the Differential Voltameter are :—

1st. The dilute acid employed in both tubes should be of equal strength.

2nd. After disuse, the equality of the resistances of the voltametres and connection should be verified by passing the current through them with equal resistances in each branch.

3rd. The battery power should be proportional to the resistances to be measured, whilst owing to the voltameter exercising an opposing electro-motive force by polarisation, less than five Daniell's elements should not be employed.

4th. The india-rubber pads should be smeared from time to time with a waxy substance such as resin cerate.

With these precautions the measurements of the instrument have been compared with a very perfect Wheatstone bridge arrangement, and tables of results are given showing that it can be relied upon to within one-half per cent. of error of observation. Its principal advantages are stated to be: that the resistance is measured in work done, and does not therefore depend upon a momentary observation, that it is not influenced by motion on board ship or by magnetic disturbances, and that its construction is so simple that each part can be easily examined and verified.

It is regarded, however, only as a useful adjunct to the more important subject of thermometry, which forms the principal object of this paper.

*THE GIGANTIC LAND TORTOISES OF THE MASCARENE AND GALAPAGOS ISLANDS**

EVER since the foundation of Natural History Collections in Europe, naturalists had their curiosity excited by shells of Tortoises of enormous size that were brought home in vessels coming from India. From the accounts of travellers as well as from the great convexity of their shell, these tortoises were known to be terrestrial in their life, and totally distinct from the other giants of the Chelonian order, the marine Turtles. Various localities having been given as their habitat, such as the Cape of Good Hope, the Coast of Coromandel, Malacca, China, &c., the impression prevailed that they were found in many parts of India, and consequently nothing could have been more appropriate than the name given to them, *Testudo indica.*

It is not the object of the present article to treat in detail of the divergent views held subsequently by zoologists, some distinguishing several species from the difference of the form of the shell alone, others maintaining that there was one very variable species only which had been carried by ships from its native place into various parts of the globe where it became acclimatised, until Dr. Gray, the principal advocate of the latter opinion, himself was compelled to admit that there must be at least two kinds, one with a convex and the other with a flat skull. The scientific study of these tortoises may be said to have commenced with this distinction, but it commenced at a time when the work of disturbance and extermination by man had already reduced the amount of evidence so far as to well nigh bring the subject into the domain of palæontological research.

From the accounts of voyagers of the sixteenth and seventeenth centuries we learn that these tortoises were found at two most distant stations, one being the Galapagos group in the Pacific, the other comprising some of the islands of the Indian Ocean; Mauritius, Rodriguez, Aldabra, and probably Réunion. Widely different as these stations are in their physical characteristics, they had that in common, that they were, at the time of their discovery, uninhabited by man or even by any large terrestrial mammal. There is not the slightest trace of evidence that any of the intervening lands or islands have ever been inhabited by them.

At first the Tortoises were found in immense numbers and of extraordinary size. Leguat (1691) says that in Rodriguez "you see two or three thousand of them in a flock, so that you may go above a hundred paces on their backs;" and indeed, when we consider that these helpless creatures lived for ages in perfect security from all enemies, and that nature has endowed them with a most extraordinary degree of longevity, so that the individuals of many generations lived simultaneously in their island home, we can well account for the multitudes found by the first visitors to those islands. For a period of more than a century they proved to be a source of great benefit to the crews and passengers of ships, on account of their excellent and wholesome meat. In times when a voyage, now performed in a few weeks, took as many months, when every vessel, for defence's sake and from other causes, carried as many people as it was possible to pack into her; when provisions were rudely cured and but few in kind, these tortoises which could be captured in any number with the greatest ease in a few days, were of the greatest importance to the famished and scorbutic ship's company. The animals could be carried in the hold of the ship for many months without food, and were slaughtered as occasion required, each tortoise yielding from 80 to 300 pounds of fresh wholesome food; and we read that ships leaving the Mauritius or the Galapagos used to take upwards of 400 of these animals on board.

Although no account of the first discovery of the Galapagos Islands appears to have been published, so much is certain that it is due to the Spaniards, who applied the Spanish word for tortoise to this group of islands. It became the regular place of meeting and refitting to the buccaneers and whalers, who provisioned themselves chiefly with tortoises and turtles. But numerous and constant as these visits were, the reckless destruction of animal life was limited chiefly to the coast-belt, and numbers of the animals inhabiting the interior escaped; no regular or extensive settlement being attempted, the condition of the islands and of the animals inhabiting them remained in the main unaltered until the earlier portion of the present century. From the accounts of that period I select that given by Porter, a Captain in the United States Navy, as the one which contains by far the most interesting observations (Journal of a cruise made to the Pacific Ocean, New York, 1822, 8°). He found, in the year 1813, the tortoises in greater or less abundance in all the larger islands of the group which he visited, viz., Hood's, Narborough, James, Charles, and Porter's Islands. On Chatham Island he found only a few of their shells and bones, which appear to have been lying there for a long time, and possibly may have belonged to individuals transported from some other island. On Albe-

* The substance of this article is contained in a paper read by the author before the Royal Society in June, 1874, which will appear in the forthcoming volume of the "Philosophical Transactions," and to which I must refer for the scientific portion and other details. Some facts which have come to my knowledge subsequently to the reading of this paper, are added.

marle Island, the largest of the group, none were observed by him, evidently because he landed here only for a few hours on the south-western point. Abingdon, Binloe's, Downe's and Barrington Islands were not visited by him. He describes the steps of the tortoises as slow, regular, and heavy; they carry their body about a foot from the ground, frequently erecting their neck, which is from eighteen inches to two feet long, and very slender; also their head is comparatively small. In the daytime they appeared remarkably quick-sighted and timid, drawing their head into the shell on the slightest motion of any object; but they are said to be entirely destitute of hearing, as the loudest noise, even the firing of a gun, did not seem to alarm them in the slightest degree. At James Island Porter took on board as many as would weigh about fourteen tons, the individuals averaging about sixty pounds, that is, about 500 individuals; and he states that among the whole there were only three males which he distinguished by their great size and by the greater length of the tail. As the females were found in low *sandy* bottoms, and all, without exception, were full of eggs, he presumed that they came down from the mountains for the purpose of laying; the few males had been taken at a considerable distance from the shore, in the hilly interior of the island. The eggs are perfectly round, white, with a hard shell of a diameter of $2\frac{1}{2}$ inches. He found the blood of the tortoises to possess constantly a temperature of 62°, whilst the general temperature of the air in the Galapagos varies from 72° to 75°.

Very significant are Porter's remarks as regards the differences of the tortoises from different islands. Those of Porter's Island he describes as being generally of an enormous size, one (not by any means the largest) measuring $5\frac{1}{2}$ feet in length, $4\frac{1}{2}$ feet in width, and 3 feet in depth. The form of the shell of the race inhabiting Charles's Island is elongate, turning up forward in the manner of a Spanish saddle, of a brown colour and of considerable thickness, whilst the tortoises of James Island are round, plump, black as ebony, and remarkably thin-shelled. The tortoises of Hood's Island, one of the smallest of the group, were small, and as regards form, similar to those from Charles's Island.

Twenty-two years had passed since Porter's Cruise, when Darwin visited the Galapagos Archipelago in the *Beagle*, in the year 1835. On his excursions in the interior he still met with large individuals, but a change by which the existence of these animals was much more threatened than by the visits of whalers, &c., had taken place. The Republic of Equador had taken possession of the Archipelago, and a colony of between two and three hundred people banished by the Government, had been established on Charles Island, who reduced the number of tortoises in this island so much that they were driven by necessity to send parties to other islands to catch tortoises and salt their meat. Also, pigs had multiplied and were roaming about in the woods in a feral state, no doubt destroying the offspring of those which hitherto had escaped.

After an interval of not quite eleven years H.M.S. *Herald* followed the *Beagle* on a voyage of discovery and survey. The naturalist of this expedition, which reached the Galapagos in the year 1846, found that the progress of civilisation had been great, or, in other words, that the displacement of the indigenous fauna by man and his companions had proceeded apace. On Charles Island the cattle had increased wonderfully, and were estimated at 2,000 head, beside wild pigs, goats, and dogs; the wild dogs keeping the goats and pigs very much down, whilst the tortoises had been exterminated between the visits of the *Herald* and *Beagle*. On the other hand, they were met with on Chatham Island, but the largest individual measured only two feet two inches in length.

Recent accounts of visits to the Galapagos do not give us the particulars of the present condition of the indigenous fauna, nor do they contain any information as regards the survivors of its Chelonians. The specimens which at rare intervals reach Europe *viâ* Panama, are young individuals not exceeding twenty inches in length or about twenty-five pounds in weight. The giants of their race appear to be extinct or nearly so, and it is scarcely to be expected that (except under most favourable conditions) any of the surviving comparatively young and small individuals of so slow-growing a form of animal life will be allowed, by an increasing lawless population, to live long enough to reach the dimensions of the individuals of former generations. Therefore, there is but little hope that valuable additions will be made to the scanty and incomplete material in our collections; and any information as regards the present occurrence of the several races in the various islands, is to be received with caution, as evidently the original distribution of the races has been much interfered with in the course of time by the carriage of tortoises from one island to the other.

The original condition and the fate of the tortoises of the Mascarene Islands were precisely the same as in the Galapagos. Their extreme abundance in the small island of Rodriguez * has been referred to above. Down to 1740 they continued to be numerous in the Mauritius; for Grant ("Hist. Maurit.," p. 194) writes in that year—"We possess a great abundance of both land- and sea-turtles, which are not only a great resource for the supply of our ordinary wants, but serve to barter with the crews of ships who put in here for refreshment on their voyage to India." But they appear to have been much more scattered in the larger islands than in Rodriguez; and, according to Admiral Kempinfeldt, who visited the latter island in 1761, small vessels were constantly employed in transporting these animals by thousands to Mauritius for the service of the hospital. Soon, however, their number appears to have been rapidly diminished; and to the causes which worked their destruction in the Galapagos, here another was added, viz., widely spreading conflagration, by which the rank vegetation of the plains was destroyed to make room for the plantations of the settler. They did not long survive the Dodo or Solitaire, and early in the present century the work of extermination was accomplished; there is at present not a single living example either in Rodriguez or Mauritius.

Our knowledge of the indigenous fauna of the Island of Réunion is still extremely meagre. If we can trust to tradition, a gigantic land-tortoise once inhabited this island; and if this be really the case, it must have become extinct long before the Mauritius and Rodriguez species, nor is there any evidence to show its affinity to one of the other races. The Seychelles do not appear to have been inhabited by these animals, certainly not within historical times, all the individuals found there having been imported from Aldabra and kept in a semi-domesticated condition.

The Island of Aldabra, the only spot in the Indian Ocean where this Chelonian type still lingers in a wild state in small and gradually diminishing numbers, lies in lat. 9° 25′ S., long. 46° 20′ E. In reality it consists of three islands, separated from one another by a deep channel about half a mile wide. They are covered with verdure, low tangled bushes interspersed with patches of white sand; two of the islands are rather low, hummocky near the centre. The middle island is slightly the largest, extending six or eight miles in length and three or four miles in breadth; it is much higher than the others, and partly covered with very high trees that may be seen eight or nine leagues from the deck of a moderate-sized ship.

ALBERT GÜNTHER

(*To be continued.*)

* Again amply testified by the rich collection of tortoise-bones made by Mr. Slater, one of the naturalists appointed by the Royal Society to accompany the Transit of Venus Expedition to Rodriguez.

NOTES

An attempt has been recently made to supply a great desideratum for naturalists residing in or visiting London, in a reading-room, in a central situation, where they may consult recent publications and current periodical literature, English and foreign. The Linnean Society has taken advantage of the excellent accommodation now afforded it in Burlington House, Piccadilly, to utilise its council-room for this object when not required for the purposes of the Society. The room is open from ten to six (or four on Saturdays) to Fellows of the Society and others properly introduced, and several tables are well supplied with the newest literature in the two branches of Biology, and others are furnished with accommodation for writing, &c. It is also in immediate proximity to the very fine library of standard works in natural history possessed by the Society, where the librarian is always in attendance. If we might make a suggestion to the Council of the Society for the further development of this very useful movement, it would be that means should be taken for a more prompt and regular supply of some of the leading foreign scientific journals, as, for instance, the *Comptes Rendus* of the French Academy, in which respect the reading-room of the Linnean Society still contrasts unfavourably with that of the Royal College of Surgeons; but the longer hours are a great advantage. The room ought to become the recognised *rendezvous* for naturalists in London.

The Royal Horticultural Society has awarded Mr. Worthington G. Smith its Gold Banksian Medal for his discovery in connection with the potato disease which we recorded last week. We refer our readers to an article by Mr. Smith on the subject in this week's Nature.

Dr. R. B. Walker, F.R.G.S., is on his way home from Gaboon (where he has resided for the last ten years) with the view of publishing his "Twenty-five years experience in Equatorial Africa." Extensively engaged in commerce and geographical research, and having visited all the principal colonies and stations on the West Coast, his contributions to our knowledge of the fauna and flora, anthropology, dialects, and natural products of commerce, ought to be valuable and certainly more trustworthy than those of transient visitors.

The International Geographical Exhibition at Paris, which was opened on the 15th inst., promises to be a decided success. An immense number of visitors have already passed through the galleries, although several nations have not yet completed their preparations, and the annexes on the Terrace du bord de l'eau are far from being ready. The objects exhibited are classed into seven groups. Group 1 has to do with geographical mathematics, geodesy and topography, and the instruments pertaining to them. Group 2 deals with hydrography and maritime geography. Group 3 embraces physical geography, general meteorology, general geology, botanical and geological geography, and general anthropology. Group 4 is rich in ancient treatises, printed and in manuscript, on geographical subjects; fantastically-designed old maps, old instruments, ethnographic collections, and geographical dictionaries. Group 5 is devoted to statistics and to social, political, and agricultural economy. Group 6 has to deal with the teaching and diffusion of geography; and Group 7 with explorations, scientific and commercial voyages, and tours in search of the picturesque. The following are some of the objects which have proved most attractive to the public:—In the Salle des Etats, where the general meeting will be held, is the map of France constructed by the staff. This map is about sixty feet high by forty wide, and many people look at it with telescopes from a distance in order to find the details which interest them. In the English section is a large map of the polar regions, showing the route which the English expedition is to follow; also a large map of the Anglo-Indian Empire, the collection of the proceedings of the Royal Geographical Society and the magnificent instruments employed by the Indian Trigonometrical Survey. The American section, in a remote part of the building, is notable for the admirable collection of the maps of the U.S. Signal Office, and the physical atlas constructed by the venerable Prof. Henry. In the Russian department are exhibited the jewels of the Khan of Khiva; a large map of Asia showing the itineraries of 150 Russian explorers who have travelled in that part of the world during the last twenty years; specimens of the map of the frontier between Russia and China; specimens of the topographical maps drawn by officers during the last Khivan expedition; a map of the Oxus, showing the old tract of the stream when it sent its waters into the Caspian as well as into the Aral Sea; a magnificent map of the Aral Sea, and a collection of geodetical and meteorological instruments. In the French section an attractive object is the complete French station used in observing the Transit of Venus at Saint Paul by Mouchez, with several specimens of photographs of the transit. There is expected from Sweden a meteorite so large that it will have to be placed outside in the Terrace du bord de l'eau; also an artificial representation of the aurora borealis, which is likely to prove of great interest. Dr. A. B. Meyer will exhibit a manuscript map of his explorations in New Guinea. This will doubtless be of great interest to geographers, as it is the first map of that region which goes into detail.

We learn from the *Scotsman* that a meeting of the General Committee appointed in Glasgow to make the necessary arrangements for the meeting of the British Association to be held at Glasgow next year, was held on Wednesday week. A letter from the assistant-secretary of the Association to Sir William Thomson was read by Prof. Young, and in the course of it the name of Prof. Sir R. Christison, of Edinburgh, was mentioned as president-elect.

The Paris Academy of Sciences on Monday last elected Capt. Mouchez to fill the place in the Section of Astronomy vacated by the death of the late M. Mathieu. The contest was unusually severe, every member of the Academy having taken part in the vote. Capt. Mouchez obtained 33 votes, and M. Wolf 26; one vote was given to M. Tisserand, the Director or the Toulouse Observatory.

General regret will be felt at the death,—which took place on Sunday,—of Lady Franklin, at the age of 83 years. Jane Griffin, for such was her maiden name, was married to the great and unfortunate Arctic explorer on Nov. 5, 1828, and accompanied him almost constantly in the fulfilment of his duties until his departure on his last Arctic voyage of discovery in 1845. She has naturally ever since taken the deepest interest in Arctic exploration, and has herself directly done much to forward it by fitting out expeditions either entirely or partly at her own expense. It was she who sent out the *Fox* which in 1857–9, under Sir Leopold M'Clintock, did important service in Arctic exploration and in the discovery of the records and relics of the unfortunate Franklin expedition. That her interest in Arctic enterprise was strong to the very last is shown by the fact that she helped to equip the *Pandora* which so recently left our shores to attempt the N. W. passage under Captain Allen Young. For her services in this direction she received on the return of the *Fox* the Gold Medal of the Royal Geographical Society; she was the first woman on whom it was conferred, the only other one who obtained such a distinction being the late Mrs. Somerville. Until within the last few years, when incapacitated by old age and illness, Lady Franklin was herself an almost constant traveller; she had made a voyage round the

world and visited many of the principal places in Europe, North and South America, Asia, and Australasia. She was, as might be surmised, a woman of superior intelligence, clear-sightedness, and great determination; her name will no doubt live alongside of that of her renowned husband.

FROM a circular letter of M. Leverrier to the Presidents of the Meteorological Commissions of the Departments of France, we learn that the "Atlas Météorologique" for the years 1872 and 1873 is in the press, and that concerted action of several departments by regions is, if slowly, yet gradually being inaugurated in different directions, particularly in the valleys of the Seine, Gironde, Rhône, and Meuse, and the Mediterranean sea-board. M. Fron resumes the discussion of thunderstorms, and M. Belgrand undertakes that of the rainfall.

IN connection with the recent disastrous inundation of the Garonne, the following heights, above low-water, of the floods of that river from 1804, as given by M. W. de Fonvielle in the *Bulletin Hebdomadaire* of the Scientific Association of France, Nos. 400 and 402, will be interesting:—July 1804, 21·7 feet; August 1809, 11·8 feet; May 1810, 21·8 feet; April 1812, 12·5 feet; June 1813, 17·8 feet; May 1815, 17·6 feet; April 1816, 16·7 feet; February 1817, 16·7 feet; November 1819, 10·9 feet; March 1821, 15·4 feet; May 1824, 16·4 feet; October 1826, 18·9 feet; May 1827, 23·3 feet; May 1830, 11·5 feet; October 1833, 17.4 feet; May 1835, 24·6 feet; March and April 1836, 13·1 feet; February 1839, 15·4 feet; April 1842, 17·1 feet; June 1845, 19·4 feet; February 1850, 18·4 feet; June 1853, 16·7 feet; June 1854, 18·0 feet; June 1855, 23·6 feet; and on the 24th June, 1875, 26·2 feet, the last being thus a foot and a half higher than any flood that has occurred in this valley during the past seventy-one years, and 3·3 feet higher than the historic flood of 1772.

PETERMANN'S *Mittheilungen* for July contain a map of Asia Minor, which by means of different colours shows the various levels of that region in metres. The map is, moreover, a useful one for general purposes, and is accompanied by a descriptive article by Freiherr v. Schweizer-Lerchenfeld.

THE same number of this Journal contains the continuation of Dr. Chavanne's valuable paper on the condition of the ice in the polar seas and the periodical changes to which it is subject. This paper is the result of a minute and careful examination of the reports of the most trustworthy observers, and contains two valuable tables, one showing the normal value of the winter and summer temperatures in fifteen of the principal polar basins, and the other the variation from the normal mean temperatures in summer and winter of the same basins for the period 1800–74. The paper is accompanied by a graphic chart illustrative of these tables, and also showing the secular variation in the condition of the ice in the Dwina at Archangelsk from 1734 to 1854, in connection with the secular variations in intensity of the Aurora Borealis from 1722 to 1870.

PETERMANN'S journal for August will contain a valuable paper by Dr. G. Nachtigal, giving a historical and descriptive account of the new Egyptian province, Dar Fur, and a brief sketch of the traveller's journey from Kuka to Khartoum. A map of the region referred to will accompany the paper, showing not only Nachtigal's route, but those of Von Heuglin and Schweinfurth.

IN connection with the Arctic papers of the Geographical Society, we recently referred to speculations on the condition of the interior of Greenland. The August number of the *Mittheilungen* will contain a paper by Dr. Rink on this subject, and on the possibility of crossing Greenland. The following are his principal conclusions:—1. The so-called interior ice is probably only a wall or rind, inside which may be found valleys free from snow and ice, and possibly even wooded. 2. All Greenland, probably, consists of a number of islands soldered together by the universal ice covering. 3. Most probably in two or three places, where the ice-fjords still disembogue, in earlier times a sound must have extended right across from the west to the east coast. 4. Glaciers and permanent snow are probably on the increase all over the land. 5. Floating icebergs are detached from the land by a sort of fall or downflow of the land-ice glaciers. Dr. Rink thinks that by means of properly constructed sledges drawn by men, and by carefully selecting a route and establishing suitable stations, the Greenland continent might be crossed from coast to coast.

WHILE so much is being done for Arctic exploration, the Germans in recent years have not been neglecting the exploration of the Antarctic seas. In 1873 the German Arctic Society of Hamburg, presided over by Albert Rosenthal, who has contributed so much to the equipment of polar expeditions, sent out an expedition to the south polar region under the command of Capt. Dallmann. Some of the results of this expedition will be found in the recently published expedition of Stieler's "Hand-Atlas," and a few details will be found in the August number of Petermann's *Mittheilungen*, especially with reference to Capt. Dallmann's exploration of Graham Land, discovered by the whaling Captain Biscoe, in 1832. Capt. Dallmann deserves credit for having added considerably to our knowledge of this hitherto little-known land. At the place where Biscoe saw nothing but what appeared a continuous coast line, Dallmann has discovered a strait from fifteen to eighteen nautical miles wide, with highlands between as far as the eye could reach, and an Archipelago of islands of about sixty nautical miles in extent, which has been named after Kaiser Wilhelm. Two other deep bays and many islands have been discovered and named, and will be found on the map already referred to.

THE prizes of the French Geographical Society have this year been awarded as follows:—A gold medal to Father Armand David, for his explorations in China and Mongolia; a gold medal to Dr. G. Schweinfurth, for his travels in North Africa; a silver medal to Abbé Émile Petitot, for his exploration of the North American region which extends from Great Slave Lake to the mouth of the Mackenzie; a silver medal each to MM. de Compiègne and Marche for their journey to the Gaboon and up the River Ogové; and the la Roquette gold medal to the family of the late Capt. Hall of the *Polaris* Arctic Expedition.

M. ADRIEN GERMAIN in the *Bulletin* of the French Geological Society discusses the propriety of having a common meridian for all nations, and comes to the conclusion that the French should decidedly not abandon the meridian of Paris as their first, as it presents all the advantages which a first meridian should have.

MR. E. W. PREVOST has succeeded Mr. Clowes as Science Master at Queenwood College, Stockbridge.

IMPORTANT changes are contemplated in the organisation of the French National University, as a new law has been adopted by the Assembly allowing, under certain conditions, the opening of free Universities.

WITH regard to Mr. Barrington's query in last week's NATURE (p. 213), relative to the sudden scarcity of blackbirds and thrushes, Mr. G. Lingwood, of Alnwick, writes that in the district where he resides, and with which he is well acquainted, there is no such scarcity. Mr. J. Preston, writing from Belfast, likewise testifies to their superabundance in that neighbourhood.

IN an octavo volume of some eight hundred pages, the U.S. Government has recently issued a handbook of the ornithology of the region drained by the Missouri River and its tributaries,

entitled "Birds of the North-west, from the pen of Dr. Elliott Coues." There are no illustrations.

WE are glad to see that among the Supplementary Estimates just issued is a re-vote of 1,000*l.* for the Sub-Wealden Exploration.

ON Tuesday, the inaugural meeting of the Royal Archæological Institute took place at Canterbury.

A FINE male Chimpanzee, which has cut its front permanent incisors and its anterior true molars, has just been presented to the Zoological Society by Captain Lees, Governor of Lagos, West Africa.

THE recently issued part of Dr. H. G. Bronn's *Thierreich* contains an account of the lower jaw and the teeth in the different orders of the Mammalia, together with numerous excellent outline drawings of the skulls of the same groups.

MESSRS. LONGMANS are preparing for publication, in three volumes, copiously illustrated, a treatise on galvanism and electro-magnetism, by Prof. Gurtav Wiedemann, translated from the second German edition, with the author's sanction and co-operation, by G. Carey Foster, F.R.S., Professor of Physics in University College, London.

THE same publishers will issue in the autumn, a text-book of Telegraphy, by W. H. Preece, C.E., and J. Sivewright, M.A., forming one of their series of "Text-books of Science."

AMONG the works Mr. John Murray will publish during the ensuing season, the following will probably be found of interest to our readers :—"Habits and Movements of Climbing Plants," by Charles Darwin, F.R.S.—"Eastern Seas, Coasts, and Harbours," being the cruise of H.M.S. *Dwarf* in China, Japan, Formosa, and Russian Tartary from the Corea to the River Amur, by Commander B. W. Bax, R.N. This book will be illustrated by a map and engravings.—"A School Manual of Modern Geography," edited by Dr. William Smith.—"A Popular Account of Dr. Livingstone's Second Expedition to Africa; the Zambezi, Lakes Shirwa and Nyassa, with illustrations."—A new edition, being the twelfth, of Sir Charles Lyell's "Elements of Geology," in two octavo volumes; and "A Natural History of Mammals, including Man," by Prof. St. George Mivart, F.R.S., forming the first part of an introduction to Zoology and Biology.

IN yesterday's *Times* will be found an extremely interesting account from Australia of a Frenchman, Narcisse Pierre Peltier, of about thirty years of age, who has been living for seventeen years among the savages of Night Island, off the north-east coast of Queensland, in lat. 13° 10′ S., long. 143° 35′ E. He was left on the island by some shipwrecked sailors when twelve years old, was treated kindly by the savages, and soon became identified with them in every respect. He is recovering rapidly the use of his mother-tongue both in speaking, reading, and writing, though he still retains some marked characteristics of savage life. He has given much information concerning the ribe among whom he lived so long; their language does not seem to have anything in common with the Malay or with any of the Papuan dialects. If judiciously treated, Narcisse might be made to yield valuable material to the anthropologist.

THE additions to the Zoological Society's Gardens during the past week include two Suricates (*Suricata zenik*) from South Africa, presented by Mr. F. Ward; two Golden Eagles (*Aquila chrysaëtos*) from Scotland, presented by Lord Lilford; a Chinese Water Deer (*Hydropotes inermis*) from China, a Sumatran Rhinoceros (*Rhinoceros sumatrensis*) from Malacca, two Scarlet Ibises (*Ibis rubra*), a West India Rail (*Aramides cayennensis*), a Common Boa (*Boa constrictor*), a Tuberculated Lizard (*Iguana tuberculata*) from South America, deposited; three Spotted Tinamous (*Nothura maculosa*) from Buenos Ayres, and two Guiana Partridges (*Odontophorus guianensis*) from Guiana, received from Southampton; a Black-billed Sheathbill (*Chionis minor*) from the Kerguelen Island, purchased; a Collared Fruit Bat (*Cynonycteris collaris*), born in the Gardens.

SCIENTIFIC SERIALS

THE *Quarterly Journal of Microscopic Science* may, at the present time, be looked upon as the representative of the most modern phase of biological thought. The current number contains articles of much more than ordinary importance. The first is by Mr. F. M. Balfour, being "A comparison of the early stages in the Development of Vertebrates." The plate which accompanies the memoir is coloured in a particularly instructive manner, which illustrates the ultimate destination of the different elements of the cellular layers of the blastoderm. Mr. Balfour's observations are in favour of the blastopore becoming neither the mouth nor the anus of the adult animal, but of its cicatrix being a weak spot at which one or the other may subsequently be more easily formed than elsewhere. The gap between the observed structure of the developing amphibian and selachian is made more simple by the introduction of a hypothetical intermediate form in which the segmentation cavity is represented as if "it were sunk down so as to be completely within the *lower layer cells*," a condition not quite easy to comprehend. Many other very important theoretical points are discussed in this particularly interesting paper.—The second paper is a reprint from the Privy Council Reports, of Dr. Klein's observations on the pathology of sheep-pox.—Mr. W. H. Jackson describes and figures a new Peritrichous Infusorian, named *Cyclochaeta spongilla*, found in a sponge from the river Chirwell.—Mr. A. A. W. Hubrecht of Leyden makes "some remarks about the minute anatomy of Mediterranean Nemerteans," including notes on the dermal tissues, nervous system, &c., of species of *Meckelia*, *Polia*, *Lineus*, *Ommatoplea*, and *Drepanophorus* (n. g.)—Prof. Lankester publishes in full his observations read before the Linnean Society, "On some points in the structure of Amphioxus, and their bearing on the morphology of vertebrata." The exact homology of the atrial chamber and of the perivisceral cavity in the Lancelet has been a fruitful source of discussion, and Prof. Lankester's study of the question throws considerable additional light on the subject. The conclusions to which his investigations lead are "first that the peritoneal cavity of the vertebrate is the same thing as the coelom of the worm and of Amphioxus; second, that the earlier vertebrate ancestors (represented in a degenerate form by Amphioxus) developed epipleura, which coalesced in the median line postorally to form an atrium; third, that whilst Amphioxus retains this atrium in functional activity, the other vertebrata have lost it by *the coalescence* of its outer and inner bounding wall, respectively epipleura and somatopleura; fourth, that whilst the indications of the earlier historical steps of this process are suppressed in all craniate vertebrata at present investigated, yet the Elasmobranchs do continue to present to us an ontogenetic phase in which the somatopleura and the epipleura are widely separated; thus enclosing between them an epicoel (the atrium of amphioxus)."—Mr. F. R. Lewis writes on Nematode Haematozoa in the dog, closely allied to *Filaria sanguinolenta*, found in the walls of the aorta. These are figured, as are the parts of *Amphiporous spectabilis* and other Nemerteans, described by Dr. M'Intosh in considerable detail. —There is an admirable paper by Prof. Thiselton Dyer, containing a review of the various modes of sexual reproduction known among Thallophytes, with a sketch of the classification of that section of Cryptogams—including Algæ, Lichens, Fungi, and Characeæ—recently proposed by Prof. Sachs.

SOCIETIES AND ACADEMIES

LONDON

Geological Society, June 23.*—Mr. John Evans, V.P.R.S., president, in the chair.—On the superficial geology of the Central Region of North America, by Mr. G. M. Dawson, Geologist to H.M. North American Boundary Commission.

Physical Geography of the Region.—The region under consideration is that portion of the great tract of prairie of the middle of North America from Mexico to the Arctic Sea, which

* Continued from p. 221.

lies between the forty-ninth and fifty-fifth parallels, and extends from the base of the Rocky Mountains to a ridge of Laurentian rocks that runs north-west from Lake Superior towards the Arctic Sea, and is called by the author the "Laurentian axis." This plateau is crossed by two watersheds; one, starting from the base of the Rocky Mountains at about the forty-ninth parallel, runs due east to the 105th meridian, when it turns to the south-east, dividing the Red River from the Missouri; the other crosses from the Rocky Mountains to the Laurentian axis near the fifty-fifth parallel. The whole region between these two transverse watersheds slopes gradually eastward, but is divisible into three prairie steppes or plateaus of different elevations. The lowest includes Lake Winnipeg and the valley of the Red River; its average altitude is 800 feet. The second, or the "Great Plains," properly so called, has an average elevation of 1,600 feet. The third or highest is from 2,500 to 4,200 feet above the sea, and is not so level as the other two.

Glacial Phenomena of the Laurentian Axis.—The neighbourhood of the Lake of the Woods is taken by the author as furnishing an example of the glaciation visible in many parts of the Laurentian axis. This lake is seventy miles long, and has a coast line of three hundred or four hundred miles. The details of its outline closely follow the character of the rock, spreading out over the schistose and thinly cleavable varieties, and becoming narrow and tortuous where compact dioritic rocks, greenstone, conglomerate, and gneiss prevail. The rocks both on the shores and the islands in the lake are rounded, grooved, and striated. The direction of the striæ is from north-east to south-west.

Drift Plateau of Northern Minnesota and Eastern Manitoba.—This plateau consists of a great thickness of drift deposits resting on the gently sloping foot of the Laurentian, and is composed to a depth of sixty feet or more of fine sands and arenaceous clays, with occasional beds of gravel and small boulders, probably reposing throughout on boulder-clay. The only fossil found was a piece of wood apparently of the common cedar (*Thuja occidentalis*). The surface of the plateau is strewn with large erratics, derived chiefly from the Laurentian and Huronian to the north; but there are also many of white limestone. The fossils in some of the latter being of Upper Silurian age, the author is inclined to believe, with Dr. Bigsby, that an outcrop of Upper Silurian is concealed by the drift deposits in the Lake of the Woods region.

Lowest Prairie Level and Valley of the Red River.—This prairie presents an appearance of perfect horizontality. The soil consists of fine silty deposits arranged in thin horizontal beds resting on till or boulder-clay. Stones were exceedingly rare. The western escarpment was terraced and covered with boulders. It is therefore probable that this prairie is the bed of a pre-glacial lake.

The *Second Prairie Plateau* is thickly covered with drift deposits, which consist in great part of local débris derived from the underlying soft formations, mixed with a considerable quantity of transported material, especially in the upper layers. Large erratics are in places abundant; they consist mainly of Laurentian rocks, but Silurian limestone also abounds. The following is the percentage of the boulders from the different formations present in the drift:—Laurentian, 28·49; Huronian, 9·71; Limestone, 54·01; Quartzite Drift, 1·14. The last is derived from the Rocky Mountains, the other three from the Laurentian axis. There are also on the surface of this plateau some remarkable elevated regions, apparently entirely composed of accumulated drift materials.

Edge of the Third Prairie Plateau, or the *Missouri Coteau*, is a mass of glacial débris and travelled blocks averaging from thirty to forty miles in breadth, and extending diagonally across the country for a distance of about 800 miles.

Third or Highest Plateau.—There is a marked change in the drift on this plateau, the *quartzite drift* of the Rocky Mountains preponderating, seldom showing much glaciation. Its general character may be seen from the following percentage of its composition:—Laurentian, 27·05; Huronian, ?; Limestone, 15·84; Quartzite drift, 52·10. Some of the lower parts of this steppe show thick deposits of true till with well-glaciated stones, both from the mountains and the east, and débris from underlying tertiary beds, all in a hard yellowish sandy matrix. On the higher prairie sloping up to the Rocky Mountains the drift is entirely composed of material derived from them.

The *Rocky Mountains* themselves show abundant traces of glaciation. Nearly all the valleys hold remnants of moraines, some of them still very perfect. The harder rocks show the usual rounded forms, but striation was only observed in a single locality, and there coincided with the main direction of the valley. The longer valleys generally terminate in *cirques*, with almost perpendicular rock-walls, and containing small but deep lakes.

State of the Interior Region of the Continent previous to the Glacial Period.—The author considers that previous to the glacial epoch the country was at about its present elevation, and that its main physical features and river-drainage were already outlined. Subaërial denudation had been in operation for a vast period of time, and an enormous mass of tertiary and cretaceous strata removed.

Mode of Glaciation and Formation of the Drift Deposits.—The author did not find any evidence rendering the supposition of a great northern ice-cap necessary, but suggests that local glaciers on the Laurentian axis furnished icebergs laden with boulders, which were floated across the then submerged prairies towards the Rocky Mountains.

On some important facts connected with the Boulders and Drifts of the Eden Valley, and their bearing on the theory of a Melting Ice-sheet charged throughout with rock-fragments, by D. Mackintosh. In this paper the main object of the author is to defend generally received opinions, especially as regards the great glacial submergence, in opposition to the theory announced in the Quart. Journ. Geol. Soc. for last February (vol. xxxi. p. 55). He brings forward a number of facts and considerations, founded on repeated observations, to show that the dispersion of Criffell granite-boulders is so interwoven with that of boulders of porphyry and syenite from the Lake-district as to be incompatible with the theory of transportation by currents of land-ice; and that the limitation of Criffell boulders along the S.E. border of the plain of Cumberland to about 400 feet above the sea-level is inconsistent with the idea of a boulder-charged ice-current 2,400 feet in thickness. His main argument against the theory of land-ice "charged throughout with rock-fragments of all sizes," is derived from the purity of the interiors of existing ice-sheets; and he quotes Prof. Wyville Thomson in support of his statements.

Observations on the unequal distribution of Drift on opposite sides of the Pennine chain, in the country about the source of the River Calder, with suggestions as to the causes which led to that result, together with some notices on the high-level drift in the upper part of the valley of the River Irwell, by John Aitken. The author, in calling attention to the unequal distribution of the drift on the opposite sides of the Pennine chain in this district, points out that on the western side of that range an extensive series of drift-deposits is found, spreading over the great plains of Lancashire and Cheshire down to the Irish Sea. It also occurs on the west flanks of the chain at elevations of from 1,100 to 1,200 feet, thus rising several hundred feet above the watersheds of some of the valleys penetrating that elevated region. On the eastern side, however, there is, with one or two slight exceptions, an entire absence of such accumulations, even in the most sheltered and favourable situations, for a distance of twelve or fifteen miles from the water-parting of the country. This absence of drift on the eastern side might, the author considers, be satisfactorily accounted for by supposing that the transverse valleys of the chain were, during the glacial epoch, completely blocked up with congealed snow or ice, by which means all communications between the opposite sides of the range would be entirely cut off. The southward flow of the ice, which was probably not so thick as to cover the higher portions of the chain, would, on encountering such an obstacle to its progress, be deflected westwards, and finally debouch into the plains of South Lancashire, and would there deposit on its retreat the débris it contained.—(*To be continued.*)

Geologists' Association, July 2.—Mr. Wm. Carruthers, F.R.S., president, in the chair.—On some of the causes which have contributed to shape the land on the North Wales border, by D. C. Davies. In a series of diagrams the author showed the probable results of an upheaving force acting upon different kinds of strata; and, in the second part of his paper, gave a detailed account of several instances, along the Welsh border, where important physical features now existing had been determined by faults and anticlinals. These were shown in a second series of diagrams in which the actual relation of numerous valleys, gorges, &c., to faults, &c., was pointed out. The various agents of erosion such as sea-water, rain-water, and ice had modified, and in some cases altered, the features due to disturbance; but the author claimed that a proper regard should

be had to all the forces of nature, both internal and external to the surface in producing the contour as it now exists.—The Yorkshire Oolites, Part II., by W. H. Hudleston.

Entomological Society, July 5.—Sir Sidney Smith Saunders, C.M.G., president, in the chair.—Mr. Dunning remarked that the *Ornithoptera* bred by Mr. Sealy from larvæ taken at Cochin, South India, and exhibited by him at a recent meeting had been identified as *O. minos*.—Mr. Bond exhibited two specimens of a *Curculio*, sent from Nova Friburgo, Brazil, which were attached to the same twig and were both attacked by a fungus. Mr. Janson said that they belonged to the genus *Hylopus*, and were well known to be subject to such attacks.—The President exhibited a lock taken from a gate at Twickenham entirely filled with the cells of a species of *Osmia*, which Mr. Smith said was, most probably, *O. bicornis*, of which he had known several instances in locks. He also exhibited an example of the minute *Hylechthrus rubri*, one of the *Stylopidæ*, parasitic upon *Prosopis rubicola*, recently obtained from briars imported from Epirus, and remarked upon a method of expanding the wings of *Stylopidæ*. He also exhibited a series of *Halictus nitidiusculus*, stylopized, and recommended entomologists on the south coast to search in August for stylopized *Halicti*, especially among thistles. Finally, he remarked on the parasites of *Osmia* and *Anthidium*, and enumerated eleven insects attacking the same species of *Osmia* in its different stages—some devouring the egg and pollen-paste, some the larvæ, and others attacking the bee itself.—Mr. Champion exhibited a series of recently captured individuals of *Chrysomela cerealis*, from Snowdon, its only known British locality. Mr. M'Lachlan stated that he had recently seen this species in the Department of Saône-et-Loire, in France, in great numbers, each ear of wheat having several of the beetles upon it, and remarked on the singular nature of its sole habitat in Britain.—The Secretary exhibited nests of a trap-door spider, sent from Uitenhage, near Port Elizabeth, Cape Colony. The nests were not (as is usual) in the earth, but in cavities in the bark of trees; and the "trap-door" appeared to be formed of a portion of the bark, thus rendering it most difficult to detect the nests when in a closed condition.—Mr. Charles V. Riley, State Entomologist of Missouri, exhibited sundry insect pests that do so much damage in the State, including the Army-worm (*Leucania impuncta*), and the Rocky Mountain Locust (*Caloptenus spretus*), and entered at some length into the habits of the latter insect and the vast amount of destitution caused by it; stating that in a short period it devoured almost every living plant, leaving nothing but the leaves of the forest trees, and converting a fruitful country into an absolute desert. From a knowledge of the habits of the insect, and believing in its inability to exist in a moist climate, he had predicted that its ravages would not extend beyond a certain line, and he had seen these predictions fulfilled. Having noticed that hogs and poultry grew excessively fat from devouring locusts, and considering that the use of them as food for man would tend to relieve some of the distress occasioned in the devastated districts; he had caused a number of them to be prepared in various ways, and they were found to be well suited for food, especially in the form of soup.—Mr. Riley also stated that he was very desirous of taking a supply of cocoons of *Microgaster glomeratus* to America to lessen the ravages of the larvæ of the genus *Pieris* on that continent, and would be greatly obliged to any entomologist who could assist him in obtaining them.—The following papers were communicated:—Descriptions of new Heteromerous Coleoptera belonging to the family *Blapsidæ*, by Prof. J. O. Westwood.—Description of a new species of Myriopod, from Mongolia, by Arthur G. Butler.—Descriptions of new *Coleoptera* from Australia, by Charles O. Waterhouse.

PARIS

Academy of Sciences, July 12.—M. Frémy in the chair.—M. Chevreul communicated the fourth extract from his third memoir "on the explanation of numerous phenomena which are a consequence of old age."—Are the disasters caused by the hurricane of 1860 near Réunion referable to the laws of Cyclones? by M. Faye.—M. J. Bertrand called the attention of the Academy to a passage in the second edition of P. Secchi's work on the sun, and made some critical remarks thereon.—Note by M. G. A. Hirn relative to the memoir of M. Kretz on elasticity in moving machines.—Theory of perfect numbers, a memoir by M. J. Carvallo.—Magneto-chemical phenomena produced in rarefied gases in Geissler tubes illuminated by means of induced currents, by M. J. Chautard. The author describes the effect of magnets in modifying the spectra of certain elements and compounds. Determinations of the wave-lengths of these modified spectra have been made for chlorine, bromine, iodine; the chloride, bromide and fluoride of silicium, boric fluoride, hydrochloric acid, antimonious chloride, bismuthous chloride, mercuric chloride, and the two chlorides of tin. The light of sulphur and selenium is immediately extinguished on "making" the magnet. Oxygen does not undergo much change. Nitrogen is modified in the red and orange. The hydrogen tube showed the D line on "making" the magnet, the line instantly disappearing on breaking contact. The author explains this phenomenon by supposing that the gas is projected suddenly against the side of the tube on magnetisation and carries away sodium particles.—On the "square mirror," an instrument for tracing right angles on the earth, and for use in the rapid measurement of great distances, by M. Gaumet.—On fused boric acid and its tempering, by M. V. de Luynes. The hardness of this substance (between 4 and 5) is between fluor spar and apatite. The powdered glass combines energetically with water, the temperature of the mixture rising to 100°. The used acid poured on to a metallic surface gives rise to the formation of a vitreous plate, of which the lower surface is more expanded than the upper, producing in consequence a bending of the plate which is sometimes sufficient to rupture it. Poured into oil, the fused acid forms small tailed drops, which break under the same conditions as "Prince Rupert's drops." A plate of the boric acid glass, with parallel faces, acts on polarised light like "toughened" glass, but preserves its property under conditions which destroy the polarising power of glass. The fused acid, placed in water, undergoes hydration by laminæ producing a true exfoliation.—On the laws of the exchanges of ammonia between the seas, the atmosphere, and continents, by M. T. Schlœsing.—Description and analysis of a mass of meteoric ore which fell in Dickson County, Tennessee, by M. Lawrence Smith. Its composition is Fe, 91·15; Ni, 8·01; Co, 0·72; Cu, 0·06. Heated *in vacuo*, two volumes of gas were given off, composed of H, 71·04; Co, 15·03; Co_2, 13·03.—Planet 146 Lucine, discovered at the Observatory of Marseilles by M. Borrelly, June 8, 1875; ephemeris calculated by M. E. Stephan.—On the temporary magnetisation of steel, by M. Bouty.—Theory of storms; conclusions. A note by M. H. Peslin.—Estimation of carbon disulphide in the alkaline sulphocarbonates of commerce, by MM. Delachanal and Mermet.—On the preparation of tungsten and the composition of wolfram, by M. F. Jean.—On some new derivatives of anethol, by M. F. Landolph.—Researches on emetine, by M. A. Glenard.—Differential ophthalmoscopic signs of disturbance and contusion of the brain, by M. Bouchut.—Of the causes of the spontaneous coagulation of the blood on issuing from the organism, by M. F. Glenard.—On the hailstorm which burst over Geneva and the Rhône valley on the night of July 7–8, by M. Colladon.—On clouds of ice observed during an aërostatic elevation on July 4, by M. W. de Fonvielle.

THURSDAY, JULY 29, 1875

PRACTICAL PHYSICS

WE propose in the present article to carry out the intention expressed in a former number (vol. xii. p. 206) of giving fuller details of the practical instruction in physics, which forms a part of the summer course of instruction given to science teachers by the Science and Art Department. The teaching of practical physics presents several difficulties, which have no doubt largely militated against its general introduction into the course of scientific education. It has not yet been systematised. Unlike practical chemistry one cannot select a practical text-book on physics and give it to the students; for such text-books do not yet exist in English. We are not forgetting the translation of Weinhold's Experimental Physics, which we lately reviewed in these columns; but that book is unsuitable for most students owing to its unwieldy size and high price.

Even if works on practical physics were at hand, another difficulty is encountered in the costly nature of the apparatus involved in studying physics. This no doubt is one of the main difficulties that the teacher has to overcome, and in this respect physics differs widely from chemistry, for it is out of the question to provide a complete set of physical apparatus for every two or three students. To meet this difficulty one may distribute different instruments among the students and allow them in turn thoroughly to master what is put before them. This plan might do for a small class, the members of which could use their fingers already. But it is at best an unsatisfactory method, for it leaves the student completely at sea directly he begins to communicate the instruction he has received, unless he can purchase what he has been in the habit of using, and this is not often within his means to do. Another course is first to teach the students how to make simple apparatus for themselves, and then to show them how to use it. The advantages of this plan are apparent. Students unaccustomed to manipulation find to their astonishment, when they begin, that all their fingers have turned into thumbs, and are amazed at their clumsiness and stupidity. Very soon, however, fingers begin to reappear, and the first successful piece of apparatus that is made gives them a confidence in themselves which they had thought impossible to attain. The pleasure of having made an instrument is increased a hundredfold when it is found that by their own handiwork they may verify some of the more important laws in physics; or make physical determinations, which before they would have considered it presumption to attempt, even with ready purchased apparatus. In order to carry out this plan successfully, minutely detailed instructions must be given to each student concerning the construction of the apparatus he has to make, and it is moreover obvious that the instruments should not take too long to make, and that the first trials should be with the simplest apparatus possible.

Let us now look at the science teachers at work at South Kensington. Each one has given to him a page of printed instructions for the day's work. These instructions have grown up within the last few years under the direction of those who have been associated with Dr. Guthrie in this undertaking, namely, Professors G. C. Foster and W. F. Barrett, together with the valuable aid of Mr. W. J. Wilson.

In the teaching of Practical Physics perhaps no subject lends itself more readily to practical work than Electricity and Magnetism; and as nearly every science student has had some little practice in this direction, this branch of physics commends itself as best fitted to begin with.

The first day's work on Electricity and Magnetism commences with the construction of simple electrical apparatus, as for example "Make a glass tube for electrical excitation;" then comes what to do in the way of cutting the tube and closing the ends. This introduces some to their first experience with the blow-pipe and the manipulation of glass, in which they rapidly gain courage and proficiency.

After this they are told to make a balanced glass tube as follows:—

"Glass tube about 12 inches × $\frac{3}{4}$ inch. Clean and dry inside, close and round one end, nearly close other end. Balance on edge of triangular file, mark centre with file. Soften one side of tube at centre with Bunsen burner, push in side with point so as to make conical cap. Avoid having file scratch at apex of cap."

Rubbers, pith balls, proof-planes are made, and the fundamental laws of electricity are tried before the day is over. Next day a gold leaf electroscope has to be made, and some capital instruments of this kind are turned out. The insulation of these electroscopes is so high that we have seen them retain a charge for an hour or more when the body of the instrument was standing in water. The secret of the insulation consists in using clean flake shellac; a little of this substance is melted in the hole through which the wire stem of the instrument has to pass, the stem is then warmed and pushed through the shellac so as to leave about a quarter of an inch thickness of shellac all round the wire. Without attempting to follow each day's work, we notice in passing that the distribution of electricity is tried by using card-board cones and cylinders covered with gilt paper, a Leyden jar with movable coatings is constructed, an electrophorus is made and various experiments tried with it, and even a Thomson's quadrant electrometer is among the more ambitious pieces of apparatus that are attempted.

Omitting Magnetism, which is not so fully developed as the other subjects, we come to Current Electricity. One of the first things that has now to be made is an astatic galvanometer, which occupies the greater part of one day's work. This instrument works so well, that for the sake of other science students we quote the following instructions for making it:—

"Wind about 50 feet of fine covered copper wire on wood block; remove wood; secure coil by tying with thread; insulate and stiffen coil by soaking with melted paraffin or shellac varnish. Make another similar coil; fix the two coils side by side on round wood block, leaving about $\frac{1}{4}$ inch space between them and soldering two of the free ends of coils together so as to make one continuous coil. Solder other two ends of wire to binding screws fixed about $\frac{1}{2}$ inch from edge of block. Lead ends of the wire also into two little hollows cut in wood block by side of binding screws, so that these depressions may serve as mercury cups; they are convenient for shunting

the galvanometer. Bend stout brass wire into flat-topped arch and fix firmly in block; the straight portion of wire at top of arch having upon it a cork roller for raising or lowering needles. Magnetise two sewing needles and fix (with opposite poles adjoining) $\frac{1}{2}$ inch apart by means of twisted fine copper wire. On same axis, $\frac{1}{4}$ inch above upper needle, fix glass thread about 4 inches long to serve as pointer. Suspend needles by silk fibre and attach fibre to cork roller. Cut card into circle 4 inches diameter and graduate circumference into degrees. Place (but do not fix) card in proper position over coil, supporting it on two corks cemented to board. Make needles as far as possible astatic. Place them in position and cover all with glass shade."

After some preliminary work with the galvanometer, a Daniell's cell and a simple form of Wheatstone's bridge are made; then a rheochord and a set of resistance coils. Then comes the following work with these instruments, in each case the necessary instructions being printed under the work to be done:—

"1. Measure relative resistances of different lengths of the same copper wire by Wheatstone's Bridge. 2. Find lengths of copper wires by measuring their relative resistances, the length of one of the wires being known. 3. Ascertain relation between resistance and weight. 4. Ascertain effect of temperature on resistance. 5. Experimentally establish the laws of divided circuits. 6. Measure the external resistance of your cell. 7. Compare the electromotive force of your cell with that of a Grove's cell."

In this direction there is, of course, an almost unlimited field for practical work, but other parts of the subject claim attention, and the time that can be given to the whole is extremely limited. Our space will not allow us to detail further what is done in electricity, nor can we give more than a hasty glance to the other subjects that are taken up in successive years by the science teachers.

Sound is not a very promising branch of Physics for practical work; nevertheless, nine or ten days are usefully spent on this subject. A monochord is the *pièce de résistance* here, and when this is made the laws of the transverse vibration of strings are verified, and the following problems solved by its means:—"1. Weigh pieces of metal of unknown weight. 2. The pitch of one tuning fork being known, ascertain that of another unknown. 3. The diameter of a German silver wire being known, ascertain its specific gravity." By means of the ordinary shilling tuning forks some useful experiments are made, and finally the velocities of sound in various solid, liquid, and gaseous bodies are determined in different ways and with a satisfactory approximation to the truth. This will indicate merely the course of practical work in sound.

Heat and Light offer more facilities for practical work. In Heat, a differential air thermometer is first made, then an alcohol thermometer is determined and graduated; the maximum density of water is tried by simple hydrometers; a bulb tube is made, and here we quote two experiments in which this bulb is used for determining coefficients of expansion:—

"Determine mean Coefficients of absolute expansion of Water and Alcohol between temperature of the day and 50° C. above.

"Weigh bulb tube filled with liquid at temperatures t and T. Calling weight of liquid at t, W and loss of weight at T, w, the Coefficient of apparent expansion is $\frac{w}{W - w}$. The real expansion is obtained by adding to this the Coefficient of expansion of the glass. (See next experiment.)

"Determine mean Coefficient of expansion of glass of thermometer tubing for 50° C. above the temperature of the day.

"Weigh bulb tube full of mercury at temperatures t and T, and so obtain Coefficient of apparent expansion of mercury ($= B$). Then assuming Coefficient of real expansion of mercury as ·00018 ($= C$), $C - B =$ mean Coefficient of glass."

The determination of specific and latent heat follows this, and a few experiments on radiant heat conclude this part.

In Light a large range of subjects is available for practical work, but the necessary instruments are more numerous, and require rather more skill in their manufacture. Nevertheless several experiments will occur to every teacher which can be made with very little preparation, such, for example, as trying the law of inverse squares, comparing in various ways the illuminating powers of different sources of light, &c. Here is something rather more difficult:—

"Make an instrument for measuring vertical heights by reflection." Instructions for this are given, and the instrument is then used for measuring the heights of ceilings, doors, &c., after it has been fully explained.

Silvering solutions are prepared and employed for many purposes; little concave and convex mirrors, for example, are made out of large watch-glasses silvered by this process of deposition, and the foci of these mirrors are then determined. A movable model is made to illustrate the law of sines; and the index of refraction of water is determined as follows:—

"Graduate slip of glass about 8 C.M. × 1 C.M. to M.M. Fix with sealing-wax two equal slips about 4 C.M. long at right angles to scale thus |——|. Place in water so that uprights are just below surface. Fix an eye-tube (blackened inside) at some distance above water and in line of scale, and note division at which top of nearest upright appears on scale. Now carefully withdraw water without disturbing apparatus, and again note division. Let height of upright be H, and distances on scale from upright respectively a and A, then $\frac{A}{H} =$ tangent of angle of incidence, and $\frac{a}{H} =$ tangent of angle of refraction. From tangent calculate sines, using formula sine $\theta = \frac{\tan\theta}{\sqrt{1 + \tan^2\theta}}$. Index of refraction $= \frac{\text{Sine of angle of incidence.}}{\text{Sine of angle of refraction.}}$ Verify result by varying angles."

A bisulphide of carbon lens is made from two watch glasses with ground edges, a notch being cut across to introduce the liquid. A bisulphide of carbon prism is not so easy to make; here is the method recommended:—

"Cut-off and grind ends of glass tube about 2 inches long × $\frac{3}{4}$ inch diameter so that planes of ends make an angle of about 60° with each other. Drill hole about $\frac{1}{8}$ inch diameter in middle of tube with hardened point of triangular file and turpentine. Glue pieces of thin sheet glass on ends. Fill with Bisulphide of Carbon and cover hole with glued paper."

By degrees a spectroscope is entirely built up, and with

it the spectra of various metallic vapours are examined till some familiarity is acquired with different spectra. Finally, a polariscope is made and different objects for examination are devised. Our space is more than exhausted, and we cannot follow the teachers further in their work. Time will, no doubt, bring greater experience and improve an already admirable course.

As we remarked in a former article, the good work done by the Department must sooner or later indirectly affect all classes. We trust the time is not far distant when the pressure of public opinion will lead men and women alike to feel but half educated if they have no acquaintance with the living facts and solid ground of nature. The happy results of such a change will soon become apparent. Already, indeed, society is becoming more interested in science. Some knowledge of the methods and results of scientific inquiry is penetrating the population. New habits of thought and modes of reasoning are spreading widely. A juster estimate of the position of the scientific explorer is being held. At the same time a truer knowledge of nature is diffusing more profound and doubtless more reverent conceptions of the orderly mystery that surrounds us.

CARUS AND GERSTAECKER'S "HANDBUCH DER ZOOLOGIE"

Handbuch der Zoologie. Von Jul. Victor Carus und C. E. A. Gerstaecker. (Leipzig: Engelmann.)

THE second volume of this work appeared in 1863, the first part of the first volume in 1868, and at length the book is completed by the appearance of the second part of the first volume in 1875. It is somewhat late in the day to review the earlier parts of the undertaking, but looking at it as a whole, we do not hesitate to say that the "Handbuch" in which Prof. Carus has had the chief share (the Arthropods alone are treated by Prof. Gerstaecker) is eminently useful and worthy of his high reputation for perspicacity and practical good sense. There are few men to whom zoologists both in this country as well as in his fatherland, are so much indebted for solid help in their labours of research or of instruction as to Prof. Victor Carus. Who has not felt grateful to him for the "Bibliotheca Zoologica," which bears his name? What naturalist of this generation has not consulted, as a storehouse of inexhaustible treasure, the "Icones Zootomicæ," which, after twenty years, continues to hold its place as the most valuable pictorial treatise on the Invertebrata which we possess? Prof. Carus has further served his countrymen by acting as the competent translator of Mr. Darwin's works—and to us he has lent timely aid by discharging for two years the duties of the Edinburgh chair of Natural History in the absence of Prof. Wyville Thomson. In an enumeration of the labours of this kind for which zoologists have to thank Prof. Carus, we must not omit the volume on the history of Zoology—published in the Munich series of histories of the sciences—a work which is full of the most interesting details of the early beginnings and strange developments of the study of animal form.

It will not be out of place, whilst strongly recommending this book to the reader as a most trustworthy, succinct, and withal ample exposition of the facts of animal morphology in especial relation to the "system" or classification of the Animal Kingdom—to say a few words as to its method and order of treatment. The first volume (that most recently published) contains the Vertebrata, the Mollusca, and Molluscoidea. The second volume treats of the Arthropoda, Echinodermata, Vermes, Cœlenterata, and Protozoa. The groups of the animal kingdom are thus discussed in a descending order, beginning with the highest: at the same time each section treating of a sub-kingdom is complete in itself. The section of the work treating of any one sub-kingdom starts with a brief definition of the group of some ten or fifteen lines in length. Then follow several pages treating of the characteristic disposition of the various organs and their variation in the following order, (1) general form, (2) integument, (3) muscular system, (4) skeleton, (5) nervous system, (6) organs of sense, (7) digestive canal, (8) respiratory organs, (9) vascular system, (10) urinary and generative organs, (11) development, metamorphoses and reproduction of parts, (12) geographical and geological distribution, (13) chief systems of classification hitherto proposed, with an outline of the classification adopted by the author, brief definitions (about ten lines each) of the classes being introduced. After this we have the detailed consideration of each class, the highest being taken first. The same method is adopted in the exposition of the characters of the class as in the treatment of the sub-kingdom—as much as twenty-four pages being thus devoted to the class Mammalia. To the class follows an enumeration of its orders, each order being *briefly* characterised in the list and then taken in turn, the highest first, for more detailed treatment. Some additional facts with regard to each order beyond those introduced in the brief definition are given when it is thus taken in its turn, and under it are placed in succession with their characteristics briefly stated, the families and sub-families and genera, the enumeration of the latter being *complete*. The principal genera are characterised—referred to their authors whilst synonyms and sub-genera are indicated. The work goes so far into detail as to cite under the genera many of the commoner or more remarkable species—with a statement of the geographical and geological distribution of the genus. After the description of an order or other large group, we usually find a bibliographical list referring the reader to the more important monographs relating to the particular group. Thus the "Handbuch" furnishes us—within the limits which are possible in an ever-growing science—with a treatise on comparative anatomy, combined with an exhaustive enumeration of the genera hitherto distinguished by zoologists, referred to a definite place in a scheme of classification. As the latest complete systematic treatise on the Animal Kingdom, and one executed with the exercise of most conscientious care, and a very exceptional knowledge of the vast variety of zoological publications which now almost daily issue from the press—this work is one which is sure to render eminent service to all zoologists. We can speak to the usefulness of the earlier volume, from an experience of some years, and there is every reason to believe that the one just completed will be found as efficient.

Having said thus much in favour of the "Handbuch," we shall proceed to point out some of its shortcomings, which

are rather theoretical than practical. Prof. Carus suffers in this book as in his "History" of Zoology, from the unphilosophic conception of the scope and tendencies of that division of Biology, which its early history has forced upon modern science. In England our newest and most conservative University continues to draw a broad distinction between what is called Comparative Anatomy and what is called Zoology. By some accident Zoology is the term which has become connected with the special work of arranging specimens and naming species which is carried on in great museums, and which has gone on in museums since the days when "objects of natural history," and other curiosities, first attracted serious attention in the sixteenth century. Accordingly Zoology, in this limited sense, has taken the direction indicated by the requirements of the curators of museums, and is supposed to consist in the study of animals not as they are *in toto*, but as they are for the purposes of the species-maker and collector. In this limited Zoology, external characters or the characters of easily preserved parts which on account of their conspicuousness or durability are valuable for the ready discrimination of the various specific forms—have acquired a first place in consideration to which their real significance as evidence of affinity or separation does not entitle them. From time to time the limited zoologists have adopted or accepted from the comparative anatomists hints or conclusions, and have worked them into their schemes of classification. But it does seem to be time in these days, when pretty nearly all persons are agreed that the most natural classification of the Animal Kingdom is that which is the nearest expression of the Animal Pedigree, that systematic works on Zoology should be emancipated from the hereditary tendencies of the old treatises, and should present to us the classes and orders of the Animal Kingdom defined not by the enumeration of easily recognised "marks," but by reference to the deeper and more thorough-going characteristics which indicate blood relationships. We have to note in the "Handbuch" the not unfrequent citation of superficial and insignificant characteristics in the brief diagnoses of taxonomic groups, which seems in so excellent a work to be due to a purposeless survival of the features of a moribund zoology that would know nothing of "insides," and still less of the doctrine of filiation. For instance, the very first thing which we are told of the Vertebrata in the short diagnosis of the group, is that they are "animals with laterally symmetrical, elongated, externally unsegmented bodies;" of the Fishes, that they have the "skin covered with scales or plates, seldom naked;" of the Mollusca, that they have a "laterally symmetrical, compressed body devoid of segmentation, often enclosed in a single (generally spirally-twisted) or double calcareous shell." It would be unjust to suggest that Prof. Carus, who long ago did so much to establish zoological classification on an anatomical basis, is not fully alive to the necessity, at the present day, of taking the wide biological view of animal morphology; but certainly the form in which parts of the book are cast, savours of the past epoch. It may be said that the object of the book is to present the "facts" of Zoology in a logical order; and that this sufficiently explains the arrangements to which objection might be taken as above, viz. the commencing with the higher instead of the lower groups, the prominent position assigned to external and little-significant characters, the absence of any recognition of the leading doctrine of modern Zoology, the doctrine of filiation. To this there is nothing to say excepting that of the very *many* logical methods of treatment possible in a handbook of Zoology, many are easy to follow out, and that one, which aims at presenting a logical classification of the kind spoken of by Mill, in which objects "are arranged in such groups, and those groups in such an order as shall best conduce to the ascertainment and remembrance of their laws," is a very difficult one to follow out. This kind of classification involves nothing less than an attempt (however inadequate) to trace the Animal Pedigree; for the laws to be ascertained and remembered are the laws of Heredity and Adaptation. We may regret then that so able a zoologist as Prof. Carus has remained in the old grooves and not ventured on to the inevitable track where Gegenbaur and Haeckel have preceded him.

It is in the same spirit that we draw attention to one or two features in the logical—or as it is sometimes called "objective"—classification adopted by Prof. Carus. He recognises the Molluscoidea as a main division of the Animal Kingdom, and places in it besides the Brachiopoda and the Bryozoa, the Tunicata. It certainly does not seem likely that in the present year (which is that which gives date to the volume containing the Molluscoidea) he would, if attempting to indicate genealogical affinities in his classification, do what he does whilst working on the old lines, namely, place the Ascidians in association with forms so remote from them as it now appears are the Brachiopods, and separate them so entirely from their blood-relatives among Vertebrates.

It is also interesting to note how the desire to frame symmetrical groups which can be easily defined in a few words, and on the other hand the desire to mark the gaps and the relative development of the branches of the genealogical tree, operate so as to lead individuals influenced respectively by one or other of those desires to propose very different changes in commonly accepted classifications. Both methods may have their use to-day, but we cannot shut our eyes to the fact that the motive in all classifications for the future must be *genealogy*. The changes proposed in J. Müller's classification of Fishes, respectively by Carus and by Haeckel, exhibit well the divergence of the tendencies of the "formal" (we cannot grant them the monopoly of the word "logical") and of the "genealogical" school. Dr. Günther of the British Museum is followed by Prof. Carus in his proposal to reduce Johannes Müller's six sub-classes of Fish, viz. Dipnoi, Teleostei, Ganoidei, Selachii, Cyclostomi, Leptocardii, to four, by the fusion of the Dipnoi, Ganoidei, and Selachii. The discovery of the Australian Ceratodus, which does not possess a special aortic branch distributed to the incipient lungs, and is different from Lepidosiren and Protopterus in the structure of its aortic bulb and its limbs, has been made the occasion for this logical or rather formal simplification. On the other hand, Prof. Haeckel wishing to show the large gap—the long series of intermediate forms—which *must* have intervened between the development of certain of the branches of the pedigree recognised by J. Müller as sub-classes of Fish, and wishing to express the *relative* distance of

these branches from one another has, first of all (and we think with no exaggerated estimate of the gap to be marked out), removed the Leptocardii altogether from association with the other fish, and not only from association with them but from association with the remaining classes of Vertebrates. They stand alone as the group Acrania, whilst the remaining Vertebrata are the Craniata. The five remaining groups of Müller's fishes find their place with the Craniata, but one group is separated within that large division as having no jaws, no limbs, and an unpaired nostril; these are the Cyclostomi, which are placed by Haeckel apart from all the remaining Craniate Vertebrates. The steps of structural differentiation which must be passed through to connect the Lampreys with the lowest of the remaining groups of J. Müller's Pisces seems to warrant this. They, the Dipnoi, Ganoidei, Selachii, and Teleostei, all belong to the large division of the double-nostrilled, jaw-bearing Craniata; but Haeckel cannot feel that the logic of his method is fully carried out, if he does not mark more emphatically the divergence of the structural characters of Dipnoi from those of the remaining and dominant classes of Fish. The class of Fishes is restricted to the three sub-classes of Selachii, Ganoidei and Teleostei; of which the first are the nearest representatives of the common ancestors of the Ganoidei and Teleostei, whilst the Dipnoi form a separate class of the Gnathostomous Craniate Vertebrata, reaching well forwards in the direction of the Amphibia, which were derived from Palæozoic Dipnoi, these in turn having been derived from Ganoidei. No doubt, it would not be possible to make any distinction between the ancestral Ganoidei and Dipnoi of Palæozoic times, had we them all before us; but that is no reason why, in framing our classifications, we should not use such breaks and divisions of groups as will best indicate in the tabular form the branching relationships of these and neighbouring organisms. The consideration of a case like the one just discussed renders it very obvious that the whole method and point of view of the naturalist who attempts to make classification the expression of the most important laws of organic structure, and therefore a genealogy, is different from that of the naturalist who endeavours to make his groups as few as may be convenient, and such that a large number of propositions can be affirmed with regard to them. The work of the latter is marred by adhesion to a conventional form, that of the former is inspired by a life-giving theory.

The absence of illustrations to Prof. Carus's "Handbuch" is not to be considered as a deficiency. In the first place, adequate illustration would immensely increase the price of the work; in the second place, we have already the "Icones," which may serve excellently as an atlas for much of the second volume. What we want now from Prof. Carus is another volume of "Icones," to contain illustrations of the Vertebrata.

E. RAY LANKESTER

OUR SUMMER MIGRANTS

Our Summer Migrants. By J. E. Harting, F.L.S., F.Z.S. (Bickers and Son, 1875.)

AMONG the many detailed differences between the lives of country and town residents there is one which has a marked influence on the lines of thought adopted by each. The townsman as a rule finds that his numerous avocations—more numerous as they must be to enable him to survive in the severer competition for a livelihood that is associated with the extra expense involved in a non-rural life—give him but little time or need for simple physical exercise as such. He has to form his ideas of the outside world by noting, as he passes through various thoroughfares, such things as attract his attention whilst he is on his way from one duty to another. When his work is over, his great idea is rest. The animated creation, humanity excepted, is a sealed book to him. The case of the country resident is very different. Either his slow-moving occupation in the open air allows him ample opportunity for looking around him, or he is compelled to "take a walk" in order to overcome the injurious influence of a sedentary employment. The charms of scenery soon, from frequent repetition, lose much of their fascination, and the observation of the surrounding changes continually occurring in the animated world become the chief objects of attraction. Of these none are more interesting than the movements of the birds, especially of those species which, instead of taking up their continuous abode with us, only condescend to visit our shores during those seasons of the year which best suit their delicate constitutions. These, our summer migrants, form the subject of the work before us; one which will be particularly attractive, as here presented, to all who have any predilections towards ornithology or the observation of natural phenomena, both on account of the valuable information it contains and the particularly elegant way in which, both typographically and as far as binding is concerned, the book has been brought out, and Bewick's accurate engravings have been reproduced.

Mr. Harting's object has not been to write a systematic work on the subject for beginners, but to collect the results of his own and other more recent observations, both as to the exact dates of arrival and departure of the migratory species of our avifauna, as well as attested facts with reference to the localities which they inhabit as their winter-quarters. Prof. Newton's new edition of "Yarrell's British Birds," Colonel Irby's "Ornithology of the Straits of Gibraltar," and the investigations of the late Mr. Edward Blyth, are amongst the most important sources from which the author is enabled to collect the observations which he classifies and employs so as to make them of special interest with regard to each individual species.

The controversy, not long ago revived, and carried on partly in this journal during 1869 and 1870 by Prof. Newton, concerning the eggs of the Cuckoo, makes the chapter devoted to that bird of special interest. On the subject of whether the hen bird is in the habit of always laying her eggs in nests of the same species of foster parent, Prof. Newton remarks (NATURE, vol. i. p. 75), "without attributing any wonderful sagacity to the Cuckoo, it does seem likely that the bird which once successfully deposited her eggs in a Reed Wren's, or a Titlark's nest (as the case may be) when she had an egg to dispose of, and that she should continue her practice from one season to another. We know that year after year the same migratory bird will return to the same locality, and build its nest in almost the same spot. Though the Cuckoo be

somewhat of a vagrant, there is no improbability of her being subject to so much regularity of habit, and indeed such has been asserted as an observed fact. If, then, this be so, there is every probability of her offspring inheriting the same habit, and the daughter of a Cuckoo which always placed her egg in a Reed Wren's or a Titlark's nest doing the like." To this Mr. Harting very justly replies—"This would be an excellent argument in support of the theory (of Dr. Baldamus) were it not for one expression, upon which the whole value of the argument seems to me to depend. What is meant by the expression 'Once successfully deposited?' Does the Cuckoo ever revisit a nest in which she has placed an egg and satisfy herself that her offspring is hatched and cared for? If not (and I believe such an event is not usual, if indeed it has ever been known to occur), then nothing has been gained by the selection of a Reed Wren's or Titlark's nest (as the case may be), and the Cuckoo can have no reason for continuing the practice of using the same kind of nest from one season to another." Mr. Harting therefore rejects the application of this principle in the case of the Cuckoo. We will suggest to him a modification of Prof. Newton's argument which may perhaps lead him to return to it in its modified form. The assumption that the bird which once successfully deposited her eggs in a Reed Wren's or Titlark's nest, would again seek for one of the same species in other seasons because of her *sagacity*, or her knowledge of its successful hatching, is highly improbable in our estimation, and not essential for the subsequent deductions, in a Darwinian point of view. It is more logical to suppose that ancestral Cuckoos deposited their eggs broadcast. That those which got into Reed Wren's and Titlark's nests (as in instances) all, or nearly all, hatched out; whilst those deposited elsewhere perished. The young *inherited* those peculiarities of the mother birds whose tendency was towards the utilisation of the Reed Wren's and Titlark's nests, and as a result the modern Cuckoo tends to place its eggs in those nests.

The evidently genuine sketch made by Mrs. Blackburn of the nestling Cuckoo ejecting the young of the Titlark along with which it was hatched, first published in the introduction to Gould's "Birds of Great Britain," is introduced as confirmatory evidence in favour of this, to the foster-brethren, murderous propensity of the young birds, with reference to which so many naturalists are still sceptical.

The peculiarity in the distribution of the Nightingale in this country is difficult to explain, especially as the Wryneck keeps within nearly the same boundaries. "When we find this bird in summer as far to the westward as Spain and Portugal, and as far to the northward as Sweden, we may well be surprised at its absence from Wales, Ireland, and Scotland; and yet it is the fact that the boundary line, over which it seldom if ever flies, excludes it from Cornwall, West Devon; part of Somerset, Gloucester, and Hereford; the whole of Wales (*a fortiori* from Ireland), part of Shropshire, the whole of Cheshire, Westmoreland, Cumberland, Durham, and Northumberland." From these data it is not difficult to recognise that with but few exceptions the Nightingale only visits those parts of this country which are covered with secondary or tertiary geological formations; and it has always seemed to us that it must be that the primary soils do not produce food suitable for the insects on which it feeds. It is true that the new red sandstone is the soil of Cheshire, and that much of Yorkshire and Derbyshire are primary formations, nevertheless the two boundaries are so similar in other respects that it is hardly possible that there is no relation between them.

There is another disputed point to which the author more than once alludes. He remarks that "we cannot help thinking that the Nightingale and many other birds which visit us in summer and nest with us, must also nest in what we term their winter-quarters; otherwise it would be impossible, considering the immense number which are captured on their first arrival, not only in England, but throughout central and southern Europe, to account for the apparently undiminished forces which reappear in the succeeding spring." The late Mr. Blyth was of an opposite opinion, and further observations are necessary before this question can be settled.

Besides the information given on subjects like the above, the nest and eggs of all the species, fifty in number, are described; whilst exact measurements are included of closely allied forms, such as the Wood Warbler, the Willow Warbler, and the Chiff Chaff; the Red Warbler, the March Warbler, &c. Their plumage and nests are also compared in detail.

To those who reside in the country and are fond of the study of nature, this work by Mr. Harting will be found as useful an addition to their libraries or their drawing-room tables, as it will be to ornithologists generally.

OUR BOOK SHELF

Meteorology of West Cornwall and Scilly, 1871 *and* 1874. By W. P. Dymond. (Reprinted from the Annual Reports of the Royal Cornwall Polytechnic Society, Falmouth.)

In the latter of these pamphlets Mr. Dymond gives an interesting discussion of the temperature range corrections for Falmouth, and an excellent *résumé* of the sea-temperature observations made at the same place during the three years 1872–73–74, which have been made with a just apprehension of the precautions which require to be taken, if observations of sea temperature are to have real scientific value. The omission of tables of daily maximum and minimum atmospheric pressure, which were given in the earlier issue, is a decided improvement; not so, however, is the omission of the table of the amounts of the rainfall, with the different winds, N., N.E., E., &c., which supply information of great value in defining local climates.

The five stations reported on are Scilly, Helston, Falmouth, Truro, and Bodmin, of which the most northern, as well as most elevated, is Bodmin. If we compare the mean temperatures of the stations for 1874, it is seen that at Bodmin the mean was 53°·3, and at Falmouth only 51°·8. In some of the months the discrepancy is still greater. Thus the mean temperature of Bodmin is about four degrees higher than that of Falmouth in each of the months from April to July inclusive, and about two degrees higher than at Truro, Helston, or Scilly. It is unnecessary to remark that these differences do not represent the differences of the climates of these places, but are to a very large extent only due to the incomparable modes of observation and of reduction of the observations adopted for the several stations. Thus, as regards the exposure of the thermometers, at Bodmin they are hung four-and-a-half feet above the ground, under a thatch

roof, facing north; at Truro they are placed on the roof of the Royal Institution, about forty feet above the ground, in a wooden shed through which the air passes freely; at Falmouth they are eleven feet above the ground, close to a wall, and in a confined situation; at Helston we are not informed how they are placed; and at the Scilly station we are only told that they "are well placed"—a statement which the observations themselves render very doubtful.

The times of observation are hourly at Falmouth, 9 A.M. and 3 and 9 P.M. at Helston, and as respects the other three stations we have no information. In reducing the observations, "corrections for diurnal range" are used in some cases, though the observations themselves show that the range corrections adopted are plainly not even approximately correct for the place.

A system of meteorological observation which would furnish the data for an inquiry into the important question of a comparison of the local climates of Cornwall requires yet to be instituted. Such a system must secure at each of the stations included within it, uniformity in exposure of instruments, uniformity in hours of observation, and uniformity in methods of reducing the observations. Till this be done, such climatic anomalies, as we have pointed out in the case of Bodmin, will continue to be published, certainly misleading some, and probably leading others to dispute the usefulness of meteorological observations.

We have much pleasure in referring to the additional meteorological information given in the tables, which is often of considerable value, particularly that supplied for Helston by Mr. Moyle, whose tables have the merit of giving the results for the individual hours of observation, as well as deductions from these.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Vibrations of a Liquid in a Cylindrical Vessel

IN NATURE for July 15, there is a short notice of a paper read before the Physical Society by Prof. Guthrie on the period of vibration of water in cylindrical vessels. It may be of interest to point out that the results arrived at by Prof. Guthrie experimentally, and many others of a like nature, may also be obtained from theory.

In the first place the fact, that the period of a given mode of vibration of liquid in a cylindrical vessel of infinite depth and of section always similar to itself (*e.g.* always circular) is proportional to the square root of the linear dimension of the section, follows from the theory of dimensions without any calculation. For the only quantities on which the period τ could depend are (1) ρ the density of the liquid, (2) g the acceleration of gravity, and (3) the linear dimension d. Now as in the case of a common pendulum it is evident that τ cannot depend upon ρ. If the density of the liquid be doubled, the force which act upon it is also doubled, and therefore the motion is the same as before the change. Thus τ, a time, is a function of d, a length, and g. Since g is $-$ 2 dimensions in time, $\tau \propto g^{-\frac{1}{2}}$, and therefore in order to be independent of the unit of length, it must vary as $d^{\frac{1}{2}}$ inasmuch as g is of one dimension in length. Hence $\tau \propto d^{\frac{1}{2}} g^{-\frac{1}{2}}$. This reasoning, it will be observed, only applies when the depth may be treated as infinite.

The actual calculation of τ for any given form of vessel involves, of course, high mathematics, the case of a circular section depending on Bessel's functions. But there is an interesting connection between the problem of the vibration of heavy liquid in a cylindrical vessel of any section and of finite or infinite depth, and that of the vibration of gas in the same vessel, when the motion is in two dimensions only, that is everywhere perpendicular to the generating lines of the cylinder. If λ be the wave-length of the vibration in the latter case,* which is a quantity independent of the nature of the gas, and $\kappa = 2\pi \div \lambda$, the period τ of the similar vibrations in the liquid problem is given by

$$\tau = 2\pi \div \sqrt{\frac{gk\,(\epsilon^{kl} - \epsilon^{-kl})}{\epsilon^{kl} + \epsilon^{-kl}}},$$

l being the depth. The formula shows that in accordance with Prof. Guthrie's observation τ diminishes as l increases, and that when l is sufficiently great

$$\tau = 2\pi \div \sqrt{gk}.$$

If x be the value of k, viz. $2\pi \div \lambda$, for a circular vessel of radius unity, then the values of x for the various modes of vibration are given in the following table extracted from a paper on Bessel's functions in the *Philosophical Magazine* for November 1872.

Number of Internal Spherical Nodes.	Order of Harmonic.			
	0	1	2	3
0	3·832	1·841	3·054	4·201
1	7·015	5·332	6·705	8·015
2	10·174	8.536	9·965	11·344

Thus if d be the diameter of the vessel, the period τ of the liquid vibrations is given by

$$\tau = 2\pi \sqrt{\frac{d}{2gx}};$$

so that if d be measured in inches, the number of vibrations per minute, n, is given by

$$n\sqrt{d} = \frac{30}{\pi} \sqrt{24 \times 32{\cdot}19 \times x}.$$

For the symmetrical mode of vibration considered by Prof. Guthrie, $x = 3{\cdot}832$, giving

$$n\sqrt{d} = 519{\cdot}4$$

agreeing closely with the experimental value, viz. 517·5. Even the small difference which exists may perhaps be attributed to the insufficient depth of the vessels employed.

This mode of vibration is not, however, the gravest of which the liquid is capable. That corresponds to $x = 1{\cdot}841$, giving

$$n\sqrt{d} = 360{\cdot}1,$$

and belonging to a vibration in which the liquid is most raised at one end of a certain diameter, and most depressed at the other end. The latter mode of vibration is more easily excited than that experimented on by Prof. Guthrie, but inasmuch as it involves a lateral a motion of the centre of inertia, it is necessary that the vessel be held tight.

The next gravest mode gives $x = 3.054$, and corresponds to a vibration in which the liquid is simultaneously raised at *both* ends of one diameter, and depressed at both ends of the perpendicular diameter. In this case the value of n is given by

$$n\sqrt{d} = 462{\cdot}7$$

Terling Place, Witham, July 15 RAYLEIGH

* Namely, the length of plane waves of the same period.

Insectivorous Plants

IF further confirmation be needed of Mr. Darwin's discovery of absorption by the leaves of the *Drosera rotundifolia*, it is afforded amply by the following experiments which I have just concluded:—

Having deprived a quantity of silver sand of all organic matter, I placed it in three pots, which I shall call A, B, and C. In each of these pots I placed a number of plants of the *D. rotundifolia* under the following conditions:—(1) Perfectly uninjured, but washed all over repeatedly in distilled water. (2) Similarly washed, but with all the roots pinched off close to the rosette, and with the leaves all buried, only the budding flower stalk appearing above the sand. (3) similarly washed, with the roots and the flower stalk left on, but all the leaves pinched off, the roots being buried in the sand. (4) Similarly washed, roots left on, four leaves buried in the sand, two leaves flower stalk, and roots left above the sand and the roots protected against the possibility of their absorbing anything from the sand. All the plants were carefully watched, so that no flies were caught.

I fed pot A with pure distilled water, B with strong decoction of beef, and C with ·0026 per cent. solution of phosphate of ammonia.

The results are briefly these, after seventeen days' experimentation: In A all the plants are growing and looking perfectly healthy, though those with four leaves buried and the roots exposed, looked sickly for a few days. Now, however, they are putting forth new leaves; so are those with all the leaves pinched off and the roots buried.

Those with the roots pinched off and all the leaves buried are bursting into flower.

In B all the plants are greatly damaged, those with the leaves only, and those with the roots only are quite dead. Those with the roots off and the leaves buried have their leaf stalks much blackened, as described by Mr. Darwin as the result of over-feeding. The pot smells strongly of ammonia.

In C the condition is very much as in A, but the growth has been much more active, for some of the plants with the roots off and leaves buried have pushed new leaves up through the sand, and those with only four leaves buried have put out numerous new leaves, and their roots are quite dry. In one of these latter I amputated the roots five days after it had been in the pot, and it is as vigorous as the rest. About ·03 of a grain of phosphate of ammonia has been supplied to this pot during twelve days for twelve plants.

It is, therefore, perfectly certain that the sun-dew can not only absorb nutriment by its leaves, but that it can actually live by their aid alone, and that it thrives better if supplied with nitrogenous material in small quantities.

The nitrogenous matter is more readily absorbed by the leaves than by the roots, for over-feeding kills the plant sooner by the leaves alone than by the roots alone. But it is also certain that the roots absorb nitrogenous matter.

On June 17 I read a paper to the Birmingham Natural History Society, in which I announced that I had been able to separate a substance closely resembling pepsine from the secretion of the *Drosera dichotoma*. Since then I have also separated it from the fluid taken from the pitchers of various nepenthes.

The secretion from the *Dichotoma* was gathered on a feather which was washed in pure distilled water. It made the water very viscid, although probably the whole amount gathered from the only available plant was not more than six or eight minims, and an ounce of water was used. One cubic centimetre of this solution to five cubic centimetres of fresh milk separated a thick viscid mass, with a very small quantity of whey, in about twelve hours, at the ordinary temperature of the atmosphere. This mixture was kept in an open test glass three weeks, but it never became putrid.

The remainder of the solution was accidulated with dilute phosphoric acid, and then a thin mixture of chalk and water was added drop by drop till effervescence ceased. The mixture was allowed to stand for twenty-four hours and the clear fluid removed.

The precipitate was treated with very dilute hydrochloric acid, and the result treated with a saturated solution of pure cholestearine made by Beneke's method, in a mixture of absolute alcohol and absolute ether. The mass which separated was then dissolved in absolute ether, and in the resulting water was suspended a greyish flocculent matter which, on examination was found to be perfectly amorphous. It was dried at a temperature of 42°, and weighed, roughly, a third of a grain. It was partially soluble in distilled water, not at all in boiling water, greatly soluble in glycerine, and it produced the characteristic viscid change on a small quantity of fresh milk.

Fluid was taken from three nepenthe pitchers which had not opened their valves, to the amount of 2·3 cubic centimetres. It was treated in the same way as described above, and yielded a trace of the flocculent matter. Seven cubic centimetres of fluid from pitchers which had been long open and contained abundant insect *débris*, yielded the same flocculent substance. It has a specific gravity fractionally greater than water, and has reactions quite similar to the substance separated from the *D. dichotoma*, and which I propose to call droserine.

At Mr. Darwin's suggestion I have tried the action of the fluid of four virgin pitchers of the *Nepenthe phyllamphora* on cubes of albumen one millimetre in measurement. After twenty-eight hours immersion there was no indication of change by any one of the four fluids. Yet the chemical differences in all four were very marked. One only was viscid, yet it contained not a trace of the grey flocculent matter which I regard as the ferment. One only was at all acid, the other three being absolutely neutral. One contained quite a large quantity of the ferment, whilst the fourth had no reaction in silver lactate, so that I imagine it was only pure water. On the contrary, fluid taken from pitchers into which flies have previously found their way is always very acid, has a large quantity of the ferment, and acts in a few hours on cubes of albumen, making them first yellow, then transparent, and finally completely dissolving them.

The quantities obtained were too small to submit to analysis, and I am not sufficiently an adept in chemical manipulation to give a better account of this interesting substance.

When studying the nepenthes, I was puzzled to see the use of the channel which exists on the back of the pitchers, and which is formed by two ridges furnished with spikes in most of the nepenthes, but not in all, which run up to the margin of the lip of the pitcher.

I found that one plant under observation was infested by a small red ant-like insect, numbers of which had found their way into one particular pitcher. I observed two or three on the leaf of this pitcher, and I carefully observed their movements. They occasionally approached the edge of the leaf, but always turned back when they encountered the spikes which run down the margin, and which are the same as are seen on the ridges. In all the mature pitchers the stalk hangs in contact with the pitcher just between those two ridges, about half way between the attachment of the stalk and the lip of the pitcher.

At this point of contact the insects marched on to the pitcher, and then, of course, found themselves on the pathway between the ridges. Here they again always turned back when they encountered the spikes, so that they soon found their way to the lip.

Here they paused, and seemed to enjoy some secretion which seems to be poured out on the glazed surface of the lip. Then they travelled onwards, and met the fate of their companions. I found about thirty of these insects in this pitcher, and as they were in various stages of digestion, I presume they were entrapped at different times. I could see no reason why they all went to this pitcher, though no doubt there was one. The secretion in which they were being digested was very viscid and very acid. In the unopened pitcher the secretion is only faintly acid and not at all viscid. The secretion is increased, therefore, as Mr. Darwin has shown to be the case in *Drosera*, in quality after food has been taken in.

The footpath extending from the petiole to the lip of the pitcher, armed on each side with a *chevaux-de-frise*, to prevent the prey wandering off, is a contrivance which is manifestly for the advantage of the plant; so also, is the umbrella which is extended over the orifices of the pitchers in many of the nepenthes. Its obvious use is to prevent dilution of their gastric juice. In some the lid does not cover the orifice; probably there is something special in their habits.

The glands which line the pitchers differ considerably from the *Dionæa*, and they are placed in curious little pockets of epithelial cells, the meaning of which is not evident.

LAWSON TAIT

Curious Phenomenon in the Eclipse of 1927

ON the morning of June 29, 1927, there will be the next solar eclipse in England in which anything in the shape of totality can be seen. In an examination of eclipses I made two or three years ago, I considered this one would be total for a brief period in the north of England, as mentioned in NATURE, vol. xii. p. 213. But the curious point worthy of notice is the following:—As the moon's disc only just overlaps that of the sun, we may expect to see the red flames visible, not as prominences, but as a line of red light encircling the sun for a few moments. The probable appearance of such a phenomenon in a slightly total eclipse of the sun was pointed out by Prof. Grant in a paper in the December Notices of the R.A.S., 1871 (q.v.) The eclipse of June 29, 1927, seems to afford such an opportunity as the Professor wished to find out. Although this eclipse, therefore, is but an apology for a total one, it may acquire an interest of its own for posterity. See my little work, "Eclipses Past and Future" (Parkers) on this subject. Spectroscopic *prévision* of Rain with a High Barometer

MY letter of last Monday (in last week's NATURE, p. 231) having been sent off when we (in Edinburgh) were still in the

midst of heavy rain, N.E. wind, high barometric pressure, and an abnormal sky-spectrum, you may be interested in hearing how matters quieted down until this Monday, when we have a delightful drying west wind, high floating clouds, and a normal sky-spectrum showing fine lines only.

On Tuesday the 20th then, there was a sensible alleviation of Monday's abnormal spectrum bands, though they were still there; and the weather, though dark, began to clear.

On the 21st and 22nd, the abnormal bands had almost disappeared, leaving the lines proper of the spectrum easily visible, and the weather was fine.

Friday, the 23rd, however, was wet by day and very wet at night; yet the sky-spectrum was good and nearly normal. Note, however, from the Meteorological Journal below,* that this rain came with a west wind, a low barometer, and a considerable fall of temperature. And the wind has been westerly ever since, and with a normal sky-spectrum.

Hence the intensification of the band on the less refrangible side of D would seem to be thus far identifiable both in London and Edinburgh with warm rain in an easterly wind and under a high barometer.

While, that the said band really was intensified to a very noteworthy degree, and quite abnormally both with respect to the broader band which appears on the *more* refrangible side of D (or over W.L.L. 5830—5680), and to other telluric manifestations, at sunset—is demonstrated now most satisfactorily by my having just heard from my friend, Prof. P. G. Tait, M.A., whom I had not seen for six weeks before, that he has been independently observing in Edinburgh the very same phenomenon, and almost at the same times, and on the same days. He was much struck too at obtaining the chief abnormal band on the most marked days from *all* parts of the sky and at all hours, and had considered what it might mean.

He has further pointed out to me since then, that Angstrom's map shows fine telluric lines in the place of the grand smoky band we observed with small spectroscopic power in W.L.L. 6000–5880; but makes them much less, instead of very much more, dark than the well-known 5830–5680 evening band; so that the question now is, what is it that *intensifies* the former and not the latter under the meteorological conditions noted?

Sea-power

I OBSERVE that a correspondent at Giessen asks (NATURE, vol. xii. p. 212) for information as to Sea-power. If he will consult Sir Robert Kane's "Industrial Resources of Ireland" he will find what he wants, with a view to what have been termed "tidal mills." A. C.

Edinburgh, July 26

OUR BOTANICAL COLUMN

THE ADELAIDE BOTANIC GARDEN.—From Dr. Schomburgk's Report on the progress and condition of the Adelaide Botanic Garden and Government Plantations during the year 1874, we gather some facts relating not only to the capabilities of the Garden in an educational point of view, but also with regard to the acclimatisation of new plants, many of which are valuable for their economical products, and others as horticultural novelties. In what is called the class ground 130 natural orders are represented and 750 genera. The plan adopted seems to be similar to that adopted in most botanic gardens, namely, by dividing the orders by strips of turf; the aquatic plants, such as the Nymphæaceæ, Vallisneriæ, Butomaceæ, Alismaceæ, &c., are arranged in a basin in the centre. Dr. Schomburgk points out what is apparent to all botanical students, that it is almost an impossibility to lay out a systematic ground perfectly, as the representatives of some orders are composed partly of natives of cool and partly of tropical countries, while other orders are solely tropical plants: the same difficulty also occurs in the lower orders of plants, such as Cryptogams. As Dr. Schomburgk says, it is to be hoped that this comparatively new feature in the plan of the Adelaide Garden will be useful to the students at the University, the foundation of which we are told is now a fact, and so promote the study of botany in South Australia. In the experimental garden great success seems to have been attained in growing the Tussack grass (*Dactylis cæspitosa*). As is well known, this plant forms a most nutritious fodder; and it is thought that if it succeeds, it will prove a most valuable acquisition to the scanty stock of good Australian fodder plants. The seed was received in Adelaide in September last, and upon being at once sown soon made its appearance above ground: the quickness of growth is said to be surprising; many of the plants in 4-inch pots showed, at the time of writing the report at the latter end of February, seventy to eighty shoots. About a dozen plants were put out in 6-inch pots, and these in the same period had as many as 123 shoots, the blades of which were remarkably sweet and soft and of a good flavour. Dr. Schomburgk says that he is convinced, though the native countries of the Tussack are much colder than Australia, it will do well in the hills; he has about 1,000 plants in pots, which are naturally sheltered part of the day from the sun, and are also watered; many of the plants are during the day more or less exposed to the sun, but he has observed no difference in their growth. It is remarkable that, notwithstanding all the pains that have been taken, both at home and in Australia, to introduce many of these useful grasses, little or no interest seems to be taken by the colonists themselves in the matter for whose benefit they are specially undertaken.

The Liberian Coffee, about which so much has been said and so much more is expected, has likewise found its way to Adelaide, four healthy plants having been received from Mr. Bull, of Chelsea. Among other economic plants recommended by Dr. Schomburgk for trial in South Australia may be mentioned the Liquorice (*Glycyrrhiza glabra*).

SUMBUL ROOT, the tincture of which is now so frequently prescribed as a stimulating tonic, had, previous to the discovery of the plant in 1869, a peculiar mystery attached to it regarding its origin, and this mystery was all the more intense from the fact that in commerce dealers distinguished Sumbul by two or three different qualities, each of which was said to be derived from different countries. Thus, the best kind was distinctly known as Russian Sumbul, and the second quality as Indian Sumbul, a variety or form of which was also known as China Sumbul, being shipped to England *viâ* China, while the Indian kind is brought from Bombay. Of the plant furnishing this Indian or Chinese product we know nothing. The root is described by Pereira in his "Elements of Materia Medica" as being of a closer texture, firmer, denser, and of a more reddish tint than the Russian sort, and of a less powerful odour. The authors of the "Pharmacographia," however, consider it "to be a root different from Sumbul," that is, the true or Russian Sumbul. The mystery regarding the botanical origin of this latter has within the last few years been cleared up by the discovery, in 1869, of living plants in the mountains near Pianjakent, a Russian town eastward of Samarcand. The Botanic Garden at Moscow was fortunate enough to receive a living plant which flowered in 1871, and was thereupon named by Kauffmann *Euryangium Sumbul*. A plant was introduced to the Royal Gardens, Kew, some two or three years since, and planted in the open ground, where it has flourished through the summer, throwing up its strong, bright green *Ferula*-like leaves, and dying down to the earth in winter, during which period it has received artificial protection. Up to the present season the plant has never flowered, but recently it has thrown up a strong and healthy umbel, some seven or eight feet high. It is only in quite recent times (1867) that the Sumbul has been admitted into the British Pharmacopœia. In the first edition, which was issued in 1864, it was not included. It has now become largely used, and its application is still increasing, being frequently administered in cases where quinine is too powerful. The root is of a soft spongy nature, with numerous interlacing fibres; it has a bitter aromatic taste, and a strong musk-like smell which it is capable of retaining for a great length of time, the specimens contained in the Kew Museum, where they have been for the last twenty-four years, retaining still the odour in a marked degree.

THE PROGRESS OF THE TELEGRAPH *

IX.

In all submarine cables the copper conductor is composed of seven small wires stranded together, an arrangement which gives much greater flexibility and strength than if a solid wire were employed. The general arrangement of the signal apparatus in connection with the cable is shown at Fig. 38. A, the battery, consists of a series of cells of Daniell's arrangement; B, the contact keys for passing the positive and negative currents into the cable; C, "switch," placing the cable in connection either with the earth, instrument, or battery as required; D, a form of Sir William Thomson's reflecting galvanometer placed in connection with the cable by switch C; E, the permanent magnet arrangement for steadying and adjusting the coil-mirror (shown in section and detail, Fig. 39); I, resistance coils interposed into the circuit

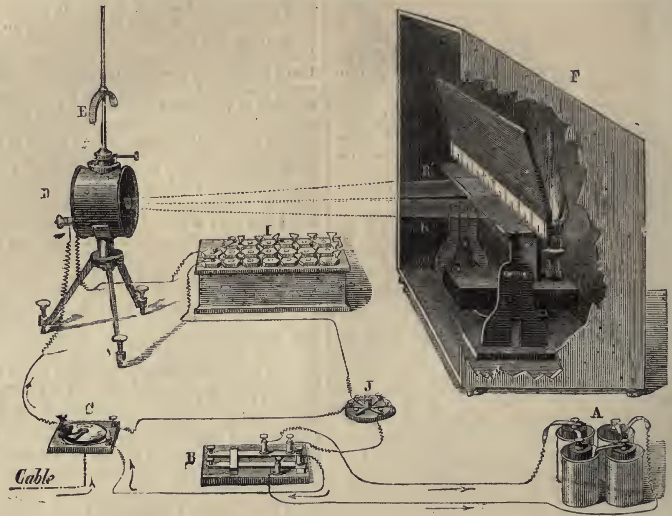

FIG. 38.—Genera arrangement of apparatus for working a submarine circuit.

between the instrument and the earth; J, a switch for connecting the line to earth; F, a darkened recess to receive the scale upon which the spot of light reflected from the lamp situated behind the partition, the ray from which, passing through a slit in the direction R is reflected back from the galvanometer mirror in the direction R′; the spot of light moves to the right or left of the zero on the scale, according as a positive or negative current is passed through the circuit; the several signals being indicated by the successive oscillations of the luminous image, signals which correspond to the conventional alphabet of the Morse system. The Morse alphabet is given at Fig. 40.

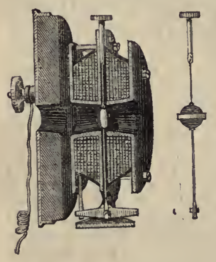

FIG 39.—Section of coil of Thomson's mirror galvanometer, showing the mirror and magnetic needle suspension.

A steam-engine without the motive power, steam, is nothing but an arrangement of iron levers, cranks, and throttle valves, useless so far as actual work is concerned. In like manner a telegraph instrument without the electric current to actuate its parts and give vitality to the circuit is valueless—a piece of apparatus to be inspected on a museum shelf. A few remarks upon "Batteries" are therefore necessary before an examination is made into the chief laws which regulate the passage of electric currents through metallic conductors.

* Continued from p. 151.

In the production of a galvanic, or voltaic current, two conditions are essential, either the presence of two metals and a liquid, or two liquids and a metal. This will be explained by reference to everyday phenomena.

FIG. 40.—The Morse Alphabetical Code.

A familiar example of the development of an electric current by two metals and a liquid is continually presented to our notice in the wasting of the iron bars of a railing close to their junction with the stone coping. Here we have the two metals, the iron composing the

railing, and the lead by which the iron is fastened into the stone, and rain or atmospheric moisture, as the liquid or exciting medium. The wasting away of the iron just above the coping stone is the result of the galvanic action set up between the two metals (iron and lead) and the liquid (the moisture of the atmosphere). To preserve an iron railing therefore it becomes necessary to dispense with the presence of lead; nothing can be better than the adoption of an iron coping in place of stone. As knowledge spreads, so practical results follow, and many modern examples of iron railings will be found to fulfil the conditions above indicated as necessary to ensure a "long life."

All connoisseurs of malt and hop beverages agree that ale drinks much sharper and is more tasty to the palate out of a pewter tankard than out of a glass. At a refreshment bar the demand is more often for "half a pint of bitter" (served in a metal vessel) than for a "glass of bitter;" and common belief in this instance is correct. Here we have a galvanic current set up by two liquids and one metal; the effect of the electric current so generated being to sharpen and improve the taste of the beverage to the palate by reason of electric action. In this example there are the two liquids—the beverage, and the saliva of the mouth—and one metal—that of the tankard—the resultant effect on the palate of the consumer being an increased life or vigour in the taste of the beverage. Thus, even in the trivialities of everyday life, electricity has a part to play. The generation of the voltaic current for telegraphic purposes is based upon one or other of these principles; and it is essential in telegraphy that the power of the current derived from the battery should be adjusted to the circuit.

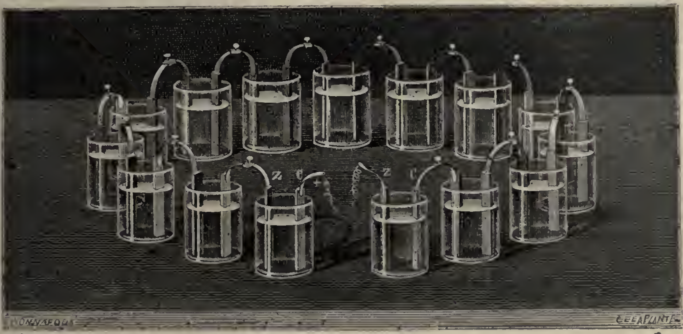

Fig. 41.—Voltaic Battery connected in series, in illustration of the *internal resistance* of the battery.

The strength of the current depends on the *electromotive force* of the battery and upon the *resistance* of the circuit. The precise meaning to be attached to these terms was first pointed out by Ohm in 1827, who showed that the strength of the current is directly proportional to the former and inversely proportional to the latter. The statement of this relation is commonly spoken of as "Ohm's Law." The total resistance of a telegraphic circuit is made up partly of the resistance of the *battery*, and its necessary connections, and partly of the resistance of the metallic conductor constituting the *line*. Consequently the law established by Ohm may be expressed as follows:—

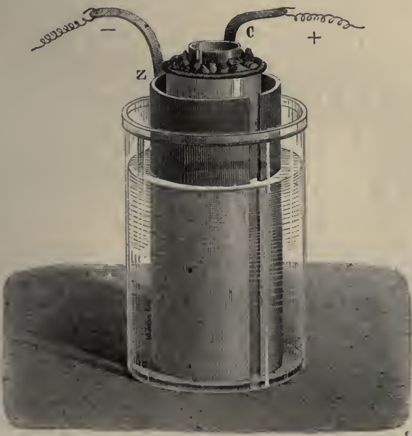

FIG. 42.—The Daniell Battery.

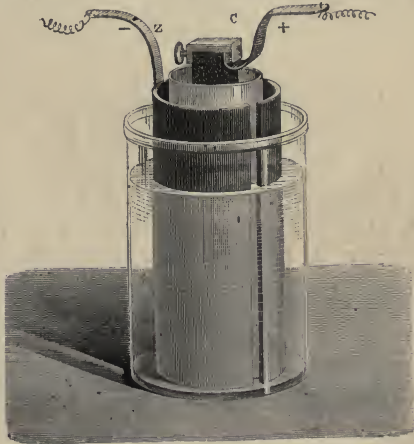

FIG. 43.—The Bunsen Battery.

The available effective force of any current = the electromotive force of the Battery—(the resistance of the Battery + the resistance of the line wire).

It has been found that in any given case the electromotive force and resistance depend upon conditions that may be thus stated:—

First, "*The electromotive force* of a voltaic circuit varies with the number of the elements, and the nature of the metals and liquids which constitute each element, but is in no degree dependent on the dimensions of any of their parts." Second, "*The resistance* of each element is directly proportional to the distances of the plates from each other in the liquid, and to the specific resistance of the liquid; and is also inversely proportional to the surface of the plates in contact with the liquids." Third, "*The resistance of the connecting wire of the circuit* is directly proportional to its length and to its specific resistance, and inversely proportional to its section." Some of the more important forms of battery in use will now be described.

Daniell's Battery, Fig. 42, consists of an earthenware or glass vessel, within which a smaller jar of some porous material is placed; the space between the inner and outer jars is filled with a dilute solution of sulphuric acid and water, and within the porous jar a saturated solution of sulphate of copper; a cylinder of zinc is immersed in the acid solution, and a cylinder of copper in the sulphate solution, crystals of sulphate of copper being introduced to maintain the strength of the copper medium. The current from this battery is remarkably constant, a matter of the greatest importance in the working of a telegraphic circuit, as with a variation in the working strength of the current, continued adjustment of the transmitting and recording apparatus is rendered necessary. Bunsen's battery (Fig. 43) in many respects resembles the Daniell arrangement; carbon is used within the porous cell in place of the copper cylinder, and nitric acid replaces the saturated solution of sulphate of copper. The current produced is stronger, but less constant than that from the Daniell's cell.

Many other arrangements for the generation of a voltaic current for telegraphic purposes are in use, such as the "Marié Davy" (Fig. 44), the "Leclanché," and "Callaud" batteries; more or less, each has its special merits and demerits: practically, the "Daniell" remains unsurpassed. The essential condition of every practical form of battery is that it shall produce a constant current be free from local action, and possess mechanical facility of renovation, with simplicity and economy of construction.

FIG. 44.—The Marié Davy sulphate of mercury Battery.

The measurement of the value of every telegraphic line as regards electrical resistance, as compared with some ascertained standard of resistance, is a matter of vast importance. By this means the electrical insulation of a submarine cable or a land wire is definitely ascertained, and the existence of a fault, together with its locality, defined. Without some established *unit* of resistance by which to compare the working circuit with its electrical equivalent, no test of insulation can be maintained or restoration of a circuit carried out. By general acceptance a standard of measurement has been adopted, a unit of resistance known as the B.A. (British Association) unit. It is unnecessary to enter into detail as to the mechanical problems which determine this unit of resistance; it is sufficient to state that the electrical resistance or value of every circuit, land wire and submarine cable, is now by universal acceptance recorded in B.A. units. For instance, a guttapercha submarine cable core may be stated to be so many hundred millions B.A. units of insulation test; while, again, an indiarubber core may be stated to be so many thousand millions of B.A. units of resistance; a correct comparison is thus at once determined.

(*To be continued.*)

OUR ASTRONOMICAL COLUMN

THE TRANSIT OF VENUS, 1882 DECEMBER 6.—The Greenwich time of first *internal* contact in this transit at any point in these islands, according to Leverrier's Tables of Sun and Planet, may be accurately found by the following equation, in which l is the geocentric latitude of the place, ρ the corresponding radius of the earth, and L the longitude, reckoned positive, if east of Greenwich, and negative, if west:—

$$\text{G.M.T. first Int. Cont.} = \text{Dec. 6d. 2h. 16m. 16s.} + [2{\cdot}5855]\ \rho \sin l - [2{\cdot}4774]\ \rho \cos l \cos (\text{L} - 85^\circ\ 58'{\cdot}6)$$

The quantities within square brackets are logarithms; the correction of course results in seconds. Direct computations for Greenwich, Edinburgh, and Dublin, furnish the following particulars of the first internal contact at these places:—

	Local Time.	Angle from N. point.	Angle from Vertex.	Sun's Altitude.
	d. h. m. s.	° ′	° ′	°
Greenwich ...	Dec. 6 2 21 2 ...	150 40 ...	128 2 ...	9·2
Edinburgh ...	„ 2 8 46 ...	150 42 ...	132 8 ...	6·5
Dublin ...	„ 1 56 8 ...	150 41 ...	132 24 ...	9·6

At Greenwich the sun sets just one hour and a half after Venus has wholly entered upon the sun's disc.

THE SUN'S PARALLAX.—M. Liais, Director of the Imperial Observatory of Rio de Janeiro, has intimated his intention to make a serious attempt to determine this important element from the very favourable opposition of the planet Mars, which will occur early in September 1877, being encouraged thereto by the success which attended his observations about the opposition of 1860, when his instrumental appliances were very inferior to what they are likely to be in 1877. The planet arrives at perihelion on the 21st of August in that year, and in opposition at midnight on the 5th of September; it is in perigee on September 2nd at a distance of only 0·3767, which is not far from the minimum, though slightly greater than in the last three repetitions of the 79-year period, as will appear from the following comparison:—

Opposition.	Mars—Mean Anomaly.
1640·64	− 0° 12′
1719·65	+ 2 31
1798·66	+ 5 15
1877·68	+ 7 58

The horizontal parallax of Mars will attain a value which, as M. Liais remarks, will be sensibly equal to that of Venus, diminished by that of the sun. With firm instruments and experienced observers, it is very probable that the amount of solar parallax may be determined by differential observations of Mars at the opposition of 1877, with a precision which may be comparable with that resulting from observations of a single transit of Venus.

A THIRD COMET IN 1813 (?).—Bode, after mentioning in his Miscellaneous Notices (*Berl. Jahrb.* 1818) that Canon Stark of Augsburg had observed the first comet of 1813 on the 19th of February, states that Stark had also discovered on the same evening with a 3½ feet Dollond telescope, a very small and exceedingly faint comet without tail above the variable star Mira in Cetus, the position of which, by comparison with the variable, he found to be at 7h. 28m. 37s., in R.A. 31° 17′ 23″, and Decl. 1° 52′ 9″ S. He saw the comet a second time on the 20th, and again comparing it with Mira, and another adjacent star, its place at 7h. 32m. 13s. was in R.A. 33° 47′ 3″, and Decl. 5° 49′ 7″ S. Cloudy skies are said to have prevented further observation. Bode remarks, with respect to this comet, that it is strange that no other astronomer had perceived it, "doch versichert Herr Stark," he adds, "noch in seinem letzten Schreiben an mich, aufs Heiligste, die Richtigkeit dieser Wahrnehmung." However suspicious this circumstance may have appeared, we know that several of the comets of short period have been revolving in such orbits for one or two centuries, visiting these parts of space without doubt under favourable

circumstances for observation on more than one occasion, yet entirely escaping detection, so that the mere fact of a single observer only having seen a comet, is hardly a sufficient argument against its existence. The late Prof. d'Arrest even thought it worth while to submit the reputed observations of the D'Angos-Comet of 1784 to further calculation, notwithstanding Encke's well-known investigation in the "Correspondance Astronomique" of the Baron de Zach, and we may have something to say on this subject in a future column. Not having seen any reference to "Stark's comet" in English astronomical works, we have given the particulars recorded of it here.

THE GREAT COMET OF 1843.—There was some doubt at the time, from the difficulty attending the determination of the orbit of this extraordinary body upon the European observations, whether it had transited the sun's disc on the day of perihelion or not. The definitive orbit calculated by a most complete investigation by the late Prof. Hubbard, of Washington, shows that a transit did actually take place on the evening of February 27, Greenwich time, and might have been observed in Australia. In next week's "Astronomical Column" we shall give the particulars of this interesting phenomenon, and reproduce Hubbard's elements with some inferences drawn from them.

D'ARREST'S COMET IN 1877.—The mean motion of this comet at the last appearance in 1870, determined by M. Leveau from an elaborate calculation of the perturbations in the two preceding revolutions, would bring this comet into perihelion again on April 17, 1877. The effect of planetary attraction in the present revolution being comparatively small, if we take this date for perihelion passage, the computed path is not likely to differ materially from the true one. It is as follows :—

Obs. Greenwich.	R.A.	N.P.D.	Distance. from Earth.
	h. m.	°	
1877 March 8	20 51	100·6	2·03
„ 28	22 6	97·2	1·94
April 17	23 16	93·2	1·89
May 7	0 25	89·2	1·89
„ 27	1 30	85·7	1·90

It would appear from this track that the only chances of observation will be with the aid of powerful telescopes in the southern hemisphere. At the last return the comet was excessively faint, and was only detected at a few of the European observatories.

THE INTERNATIONAL GEOGRAPHICAL EXHIBITION

THE idea of holding an International Geographical Exhibition at Paris, the opening of which we announced last week, in connection with the Geographical Congress which opens in a day or two, was a happy one, and has so far been fruitful in results. The catalogue of articles exhibited covers about 450 octavo pages, and the daily number of visitors reaches thousands ; last Sunday it was 12,000, including the Sultan of Zanzibar, and other visitors of all ranks and classes of society. No better method could have been adopted of showing the advances made in geography in recent years ; how from being a mere record of "hairbreadth 'scapes by flood and field," it has become a complicated science, or rather meeting-ground of all the sciences ; for, as the equipment of and instructions to the English Arctic Expedition show, it requires the aid of all the sciences to do its work well, and in return carries contributions back to them all. We have no doubt that the great majority of the visitors to the Exhibition will be astonished that geography has so many and so varied apparatus and results to show, and we hope that the Exhibition and Congress will be the means of awakening in France, as well as in other countries, an increased interest in geography, lead to its being raised to a higher platform in education, and to its being taught in a more comprehensive and more scientific way than hitherto. No doubt this will be but the first of a series of such exhibitions and congresses, though probably not annual, and we hope that the next one will be held in London. We think they are well calculated to give a strong stimulus to the scientific study of geography.

The arrangements of the Paris Exhibition make it accessible to all classes, the price of admission in some cases being as low as a penny. The articles are arranged mainly according to countries, Britain occupying but a comparatively narrow space in the catalogue. While Russia has 42 pages, Sweden, Norway, and Denmark about 40, Holland 30, Austria and Hungary 44, Great Britain and her Colonies cover only 9 pages. Even Germany has only 12 pages allotted to her. These apparent anomalies no doubt arise from some imperfections in the preliminary arrangements, and are probably to be looked for in first attempts of this kind ; no doubt the organisers of the next Geographical Exhibition will profit by the defects of the present, and have one complete all round.

As our readers are aware, the objects exhibited are classified into seven groups ; an indication of what is included in each group will convey some idea of the nature of the objects exhibited, as well as of the comprehensive nature of modern geography.

Group I., Mathematical Geography, Geodesy, and Topography, includes of course instruments of practical geometry, surveying, topography, geodesy and astronomy ; tables of projection and calculation, maps according to the various systems of projection, sidereal maps, maps of triangulation, maps showing the curves of magnetic declination, &c. In the second group, that of Hydrography and Maritime Geography, is included a great variety of instruments besides those used on board all sea-going ships ; there are dredging and sounding apparatus with specimens of what is brought up from the sea-bottom, sounding thermometers and charts, and publications of various kinds. The third group is an interesting one ; it includes Physical Geography, General Meteorology, General Geology, Botanical and Geological Geography, and General Anthropology. These are illustrated by instruments used in the observation of the principal meteorological phenomena, by maps, atlases and globes representing the essential facts belonging to the domain of Physical Geography, Meteorology, and the other sciences referred to, as well as publications bearing upon them. In group IV., that of Historical Geography, History of Geography, Ethnography, and Philology, are included, works and MSS., ancient and modern, bearing on these subjects, ancient globes and maps, antiquated instruments, ethnographic collections, and dictionaries of geography.

As might be expected, the fifth group, Economic, Commercial, and Statistical Geography is a large and varied one ; it includes works and maps bearing on population, agriculture, industry, commerce, ways of communication, ports, colonisation, emigration, &c., plans and models of bridges, tunnels, railways, routes, telegraph lines ; new apparatus for piercing rocks, manufactures or mineral objects peculiar to any country, collections of all kinds of commercial products, machinery used in manufactures of such products, produce and apparatus of deep-sea fishing, &c. Group VI., Education and the Diffusion of Geography, includes of course works, maps, charts, globes, models and instruments of various kinds, and deserves the attention of all engaged in education. Group VII. comprehends Explorations, Scientific, Commercial, and Picturesque Voyages, and, as might be expected, includes a great variety of objects. There are astronomical, topographical, meteorological, and photographic instruments of various kinds ; collections of every kind bearing on voyages of exploration, including cooking apparatus and drugs ; native implements and

weapons; tents and boats of various kinds, special instruments and apparatus for polar expeditions, &c., not to mention narratives and publications of every kind relating to voyages.

How varied the programme of this exhibition is will be seen from the above, as well as the fact that the geography of the present day is a very complicated and all-embracing province of knowledge indeed.

It is impossible here to analyse in detail the exhibits of each country; we can only at present refer to some of the objects which, as we learn from a correspondent, have attracted considerable attention.

The fine set of instruments for travellers exhibited by our Royal Geographical Society, and invented by Capt. Georges, R.N., seems to have excited considerable attention; it includes a double pocket sextant, an artificial horizon, and a barometer; the latter especially, on account of its ingenious construction, making it useful in mountaineering, is said to have attracted the attention of the New French Alpine Club.

From Norway comes a very simple declimeter having a crank working on a small notched wheel which multiplies by ten the number of degrees on the limb on which the readings are taken; a close approximation can thus be obtained by a very simple contrivance.

A Russian marine officer has sent a compass magnificently fitted up, and a lead for taking soundings, and samples of the bottom in lakes and shallow seas. It was used with success on Ladoga, the Caspian, and the Baltic. The apparatus is very simple, cheap, and not ponderous.

Mohn's map of churches struck by lightning in Norway is exhibited in order to illustrate the special danger of lightning to churches. It shows that two churches in every three years are struck and one of the two is utterly destroyed, and that in a climate where thunderstorms are relatively infrequent.

Sweden exhibits two wonderful pieces of apparatus. The first is a meteorograph for printing in numbers the degrees of dry and wet bulb thermometer, barometer, and the force of the wind. The types are placed on wheels which are moved every quarter of an hour by electricity. The barometer is a syphon one, and the thermometers open by the top a needle which descends every quarter of an hour into the mercury and gives the degree. The apparatus works regularly at the University of Upsal and at the Vienna Observatory, where the readings have been found quite correct. The printed sheets obtained at Upsal are posted on the wall of the Geographical Exhibition.

A Swedish engineer has invented a machine to show where to find beds of iron ore, and to determine also the depth to which it is necessary to descend. The miracle is performed by tracing on a map isodynamic magnetic curves, with a compass exposed to the perturbating influence of a magnetic needle placed at a distance. Two systems of isodynamic curves are to be traced, and the distance between both centres is proved to indicate the depth. Experiments and explorations with this extraordinary instrument have proved successful.

The Belgian universal meteorograph, as used in Ghent, is said to be the great success of the Exhibition. It is expected to create a revolution in weather-warnings and in meteorology generally, and will leave the famous Greenwich registering apparatus far behind. A reading is taken every quarter of an hour and engraved on copper ready for going through the press. The inventor is M. Van Rysselberghe, Professor to the Navigation School of Ostend.

The members of the several juries visited the galleries of the Exhibition on Monday last for the first time. Many members of the Academy of Science—MM. Leverrier, Faye, Quatrefages, and others—were present, as well as the foreign commissioners. We hope to give further details next week.

THE REGULATION OF RIVERS

THE recent disastrous floods in France and England call attention to the question whether it is practicable so to regulate the flow of the water in rivers as to prevent, or at least greatly diminish, such misfortunes for the future. Facts and numerical data exist which show that such regulation is practicable with much less difficulty and cost than would be thought by any one who had not made the necessary calculations.

It is perhaps scarcely necessary to say that the method of keeping the floods off the lands by means of embankments, which is the only possible resource when we have to contend against the sea or tidal rivers, is totally inapplicable to the case of the inundations of mountain streams like the Garonne. There need not be any difficulty as to the strength of the embankments, but it would be impracticable to make them high enough to contain between them such torrents as that of the Garonne when in flood. The only way in which mountain torrents can be regulated is by constructing reservoirs to retain the flood-water: and the more this plan is looked at, the more feasible it will appear.

We shall first refer to a paper by Charles Ellett, jun., C.E., on "the Physical Geography of the Mississippi Valley, with suggestions for the improvement of the navigation of the Ohio and other Rivers," forming part of the "Smithsonian Contributions to knowledge" for 1851, published by the Smithsonian Institution, Washington.

This paper contains the tabulated results of an elaborate series of observations made by the author in the spring and summer of 1849 on the flow of the Ohio, at Wheeling, between Pittsburg and Cincinnati. The flow varied from 10,158,000 cubic feet per hour, with a depth of 2.20 feet on the bar at Wheeling, to 736,000,000 cubic feet, with a depth of 31·25 feet on the bar.

"The average volume of water annually flowing down the Ohio is 835,000,000,000 (eight hundred and thirty-five thousand million) cubic feet. This volume would fill a lake 100 feet deep and $17\frac{1}{3}$ miles square. To have regulated the supply of the river in 1848, so as to have kept the depth on the bar at Wheeling uniform throughout the year, would have required reservoirs capable of holding 240,000,000,000 cubic feet, which is equivalent to a single lake 100 feet deep, and $9\frac{1}{3}$ miles square. There is no difficulty, on any of the principal tributaries of the upper Ohio, in obtaining reservoirs capable of holding from twelve to twenty thousand millions of cubic feet. It can scarcely be doubted that twelve or fifteen sites for dams may be selected capacious enough to hold all the excess of water, and equalise the annual discharge so nearly that the depth may be kept within a very few feet of an invariable height."

To control the floods of the river, however, much less than this would be needed. Mr. Ellett takes the case of the flood of March 1841, as being that in which the greatest quantity of water passed down of all the floods concerning which he has information. He takes 25 feet of depth on the bar as the high-water mark, above which the river is in flood; he estimates that during nine days of flood the river passed down 159,000,000,000 cubic feet of water, while during the same time, had it been steady at the high-water mark, the discharge would have been only 115,000,000,000. If consequently the excess of 44,000,000,000 had been kept back in reservoirs, the flood would have been prevented.

The volume it is here proposed to deal with—44,000,000,000 cubic feet—is "just equal to the quantity the river would discharge in fifty days when there is a depth of five feet in the channel."

The valley of the upper Alleghany, one of the tributaries of the Ohio, is about a third of a mile in width. A dam from 55 to 60 feet in height, thrown across the trough of this valley, so as to submerge not only the main

valley but its branches, would, according to Mr. Ellett, "probably form a lake covering from 16 to 18 square miles, with an average depth of nearly 30 feet, and containing more than 12,000,000,000 cubic feet of water." "It follows then that we should need but four dams, such as we have described, to secure the valley of the Upper Ohio against all destructive floods.

This however assumes that at the beginning of a flood the reservoirs will be empty—a condition on which it would not be safe to rely. It also seems that the shape of the valleys of the tributaries of the Ohio is everything that could be wished by an engineer who desired to convert them by means of dams into artificial lakes. They are trough-shaped, moderately wide, long, and not too steep. This last is a great advantage, because the steeper the valley the shorter is the lake that will be formed by a dam across it. It is likely that the Garonne and its tributaries are less favourably circumstanced, but nevertheless in a country of such varied contour as the south-west of France, there must be many eligible sites for reservoirs. In another way also the Garonne will certainly be found a less manageable river than the Ohio, namely that the volume of its floods bears a much higher ratio to its ordinary flow.

After the disastrous floods of the Loire in 1855, the late Emperor wrote a letter to his Minister of Public Works recommending the control of the floods by means of a number of small reservoirs to be formed by building dams across the mountain valleys. This however was lost sight of, and we see the result in the ruins of Toulouse.

A most useful work of this kind has been in operation for many years in Ireland. The following particulars are taken from a paper "on the Industrial Uses of the Upper Bann River," by John Smyth, jun., C.E., read at the Belfast Meeting of the British Association last year, and ordered by the General Committee to be printed *in extenso*.

The purpose of the reservoirs on the Bann is not to prevent floods, which, so far as we are aware, were never particularly disastrous on that river, but to equalise the flow of the river for water-power. "In 1835 the principal mill-owners formed themselves into a provisional committee to take steps to procure a better and more regular supply of water by the construction of reservoirs. They placed the matter in the hands of Sir William Fairbairn, who, assisted by J. F. Bateman, Esq., surveyed the collecting grounds of the river Bann and its several tributaries." Under their advice two reservoirs were constructed at Lough Island Reavy and Corbet Lough.

The Lough Island Reavy reservoir is 250 acres in extent, and contains 270,000,000 cubic feet. It cost 15,000*l.* to construct, besides 6,000*l.* for land. It is 430 feet above the sea-level, and is supplied by two mountain-streams. Its drainage area, including the lake itself, is only about five square miles, and it is filled and emptied only once in the year.

The Corbet reservoir is lower down than the other, and is chiefly filled from the Bann itself. Its extent is 70 acres, and its capacity 28,000,000 cubic feet. It "has been of much more service than its capacity would lead one to expect, as it may be filled and emptied four or five times in each year by small floods in the river, and all the Sunday water can be sent into it, and let down to the mills on Monday and Tuesday. It is generally exhausted before the upper reservoir is called on, and keeps up a supply when there is a scarcity in frosty weather."

The purpose of regulating the supply has been tolerably well attained. "A register of the daily height of the water in Lough Island Reavy has been kept since 1847. It shows that this reservoir has been of great service, as during 26 years an average supplementary supply of about two-fifths of the standard summer discharge allowed over Ervin's Weir, or about 30 cubic feet per second, has been granted, for, on an average, 102 days yearly: and the reservoir has been empty, on an average, eleven and a half days yearly." "The register of the Corbet reservoir has not been kept so long or so accurately as that of Lough Island Reavy; from the average of three years, however, and comparison with the register of Lough Island Reavy, I calculate it has given 120,000,000 cubic feet in the year, exactly one half that of Lough Island Reavy, or a good supply for fifty-one days; add to this the Lough Island Reavy supply, and there is a total of 153 days of twenty-four hours each." "As the supply from the reservoirs has only failed, on an average, eleven and a half days yearly, the standard water power may be said to have been almost constantly maintained:—indeed it is almost as good as steam-power, but at much less cost."

The income of the Company which has made the reservoirs is derived from a charge authorised by their Act of Parliament of 10*l.* per annum per foot of fall occupied by manufactories, and half of this when occupied by flax scutching mills and country corn-mills. The total fall from the upper reservoir to the bottom of the lowest fall is 350 feet, of which 180 are occupied by machinery. The capital of the Company is 31,000*l.*, and the dividend about three per cent., with a certainty of increase, if the advance in the price of coals, and the expected opening of the higher part of the district by railway, lead to more of the falls being occupied.

We think the calculations we have quoted from the American engineer, and the example of what has been done on a comparatively small scale in Ireland, are enough to show that the most difficult problems of the regulation of the flow of rivers may be approached with great hope of success.

THE GIGANTIC LAND TORTOISES OF THE MASCARENE AND GALAPAGOS ISLANDS*

II.

Although the island of Aldabra is a British possession, its distance from the Mauritius and the Seychelles renders a supervision on the part of the Government very difficult, and no control whatever can be exercised on crews of ships who land there chiefly for the purpose of cutting wood, which they require for curing fish, &c. Information having reached England in the course of last year that it was intended to lodge permanently wood-cutting parties on the island, the speedy extinction of the tortoises seemed imminent; and the time to prevent this seemed all the more opportune, as the then Governor of the Mauritius, Sir Arthur Gordon, was known to take great interest in all matters relating to natural history. Consequently the following memorial was addressed to him, signed by the presidents of the Royal and Royal Geographical Societies, and other men of science who had made researches into the extinct fauna of these islands:—

To His Excellency the Hon. Sir Arthur Hamilton Gordon, K.C.M.G., Governor and Commander-in-Chief of Mauritius and its dependencies.

We, the undersigned, respectfully beg to call the attention of the Colonial Government of Mauritius to the imminent extermination of the Gigantic Land Tortoises of the Mascarenes, commonly called "Indian Tortoises."

2. These animals were formerly abundant in the Mauritius, Réunion, Rodriguez, and perhaps other islands of the western part of the Indian Ocean. Being highly esteemed as food, easy of capture and transport, they formed for many years a staple supply to ships touching at those islands for refreshment.

* The substance of this article is contained in a paper read by the author before the Royal Society in June, 1874, which will appear in the forthcoming volume of the "Philosophical Transactions," and to which I must refer for the scientific portion and other details. Some facts which have come to my knowledge subsequently to the reading of this paper, are added. Continued from p. 239.

3. No means being taken for their protection, they have become extinct in nearly all these islands, and Aldabra is now the only locality where the last remains of this animal form are known now to exist in a state of nature.

4. We have been informed that the Government of Mauritius have granted a concession of Aldabra to parties who intend to cut the timber on this island. If this project be carried out, or if otherwise the island is occupied, it is to be feared, nay certain, that all the tortoises remaining in this limited area will be destroyed by the workmen employed.

5. We would, therefore, earnestly submit it to the consideration of Your Excellency whether it would not be practicable that the Government of Mauritius should cause as many of these animals as possible to be collected before the wood-cutting parties or others land, with the view of their being transferred to the Mauritius or the Seychelle Islands, where they might be deposited in some enclosed ground or park belonging to the Government, and protected as property of the Colony.

6. In support of the statements above made and the plan now submitted to the Mauritius Government, the following passages may be quoted from Grant's "History of Mauritius" (1801, 4to.) :—

"We (in Mauritius) possess a great abundance of both land and sea turtle, which are not only a great resource for the supply of our ordinary wants, but serve to barter with the crews of ships" (p. 194).

"The best production of Rodriguez is the land-turtle, which is in great abundance. Small vessels are constantly employed in transporting them by thousands to the Isle of Mauritius for the service of the hospital" (p. 100).

"The principal point of view (in Rodriguez) is, first, the French Governor's house, or rather that of the Superintendent, appointed by the Governor of the Isle of France, to direct the cultivation of the gardens there and to overlook the park of land-turtles. Secondly, the park of land-turtles, which is on the sea-shore facing the house." (p. 101.)

7. The rescue and protection of these animals is, however, recommended to the Colonial Government less on account of their utility (which nowadays might be questioned in consideration of their diminished number, reduced size, and slow growth, and of the greatly improved system of provisioning ships which renders the crews independent of such casual assistance), than on account of the great scientific interest attached to them. With the exception of a similar tortoise in the Galapagos Islands (now also fast disappearing), that of the Mascarenes is the only surviving link reminding us of those still more gigantic forms which once inhabited the Continent of India in a past geological age. It is one of the few remnants of a curious group of animals once existing on a large submerged continent, of which the Mascarenes formed the highest points.

It flourished with the Dodo and Solitaire, and whilst it is a matter of lasting regret that not even a few individuals of these curious birds should have had a chance of surviving the lawless and disturbed condition of past centuries, it is confidently hoped that the present Government and people who support the "Natural History Society of Mauritius" will find the means of saving the last examples of a contemporary of the Dodo and Solitaire.

London, April 1874

[*Hree follow the signatures.*]

This memorial was most favourably received by Sir A. Gordon, who in his reply states that, although the intention of conceding the island to parties for the purpose of cutting wood had not yet actually been carried out, the extermination of the tortoises is proceeding quite as rapidly as if this were the case. Not only are the animals destroyed by the whalers, but (as he was informed by visitors to the island) the pigs, which are supposed to have been left there by a passing ship some years ago, and which have rapidly multiplied, turn up the eggs in great numbers, and even devour the very young tortoises. The lessee should be bound to protect the animals and to remit annually to Mauritius a pair of living ones which, with others acquired by purchase, would be preserved in a paddock of the Botanic Gardens at Pamplemousses. He adds that in several of the Seychelle Islands such paddocks exist, the young tortoises being esteemed as articles of food ; at four years they appear to be considered fit for eating ; but he never observed that any are allowed to grow up as breeding stock to replace the original pair.

We confidently hope that Sir A. Gordon's successor will not lose sight of this matter and that the Royal Society of Arts and Sciences of Mauritius, to whom a copy of the memorial has been sent, with the request to support the appeal of their fellow-labourers in England, will recognise it as one of their duties to watch that the existence of one of the most interesting animal types within the limits of their own special domain, is not only prolonged but insured for all times.

We owe it chiefly to the kind mediation of Sir A. Gordon that a living pair of the Aldabra Tortoises are at present in London. Anxious to acquire this pair for the collection of the British Museum, the male being known to be the finest individual of the species in existence, I requested Sir A. Gordon to assist me in their acquisition, the owner being at first reluctant to part with them. To the excellent arrangements of the Hon. C. S. Salmon, Chief Commissioner of the Seychelles, and to the most fortunate circumstance that Dr. Brooks, the Government Medical Officer, accompanied and took charge of the animals on their journey to Europe, we have to thank that they arrived in the most perfect state of health. The Zoological Garden being clearly the most appropriate place for them during their lifetime, I handed them over to the Zoological Society, and have no doubt that, with the interest taken in this subject by Mr. Sclater, and with the care bestowed on them by Mr. Bartlett, these animals have a better chance of surviving their transmission into our severe climate than the specimens imported some thirty or forty years ago.* Mr. Salmon writes that both the tortoises are natives of Aldabra, though not of the same breed. The larger, the male, has been in the Seychelles for about seventy years ; its last proprietor, M. Deny Calais, kept it with the female in a semi-domesticated state on Cerf Island. His weight is about 800 lbs. ; the length of the shell 5 ft. 5 in. (in a straight line), the width 5 ft. 9 in. ; † circumference of the shell, 8 ft 1 in. ; circumference of fore leg, 1 ft. 11 in., and of hind leg, 1 ft. 6 in. ; length of head and neck, 1 ft. 9 in. ; width of head, 6 in. The female is much smaller, and I have no information as regards the time she was brought to the Seychelles. The length of her shell is 3 ft. 4 in., the width 3 ft. 10 in., the circumference 5 ft. 4 in. She lays thrice every year, in the months of July, August, and September, each time from fifteen to twenty round hard-shelled eggs. There is every reason to believe that the laying of eggs will not be interrupted by the transmission of the animals to England.

Every one who sees these two tortoises side by side is at once struck by the great difference in form and sculpture of the shell. That of the male is remarkably high, with a rounded outline, each plate being raised into a hummock, and deeply sculptured with concentric furrows along the margins. The female, on the other hand, has a perfectly smooth shell with an oval outline, without either furrows or raised portions. The shell of the male is brownish, that of the female black. The male has also a comparatively longer neck and tail than the female. It is quite possible that these are sexual differences, the males being known to grow to a much larger size than the females. But as Aldabra consists of three islands, separated by channels of the sea which are impassable barriers to animals which may float but cannot swim, it may be presumed that the two animals come from distinct islands, each island of the group being inhabited by a distinct race, as in the Galapagos. This is a question

* I have kept young specimens of the Aldabra Tortoise (two of which are the offspring of the very individuals now imported), as well as half-grown ones of the Galapagos species, for years. Want of water and a twenty-four hours' exposure to a temperature below 50° are fatal to them. In the autumn and winter they must be kept in a greenhouse where the temperature should be kept at about 70°. With a plentiful and varied supply of vegetables, they thrive well and grow perceptibly.

† A large example, probably of the Rodriguez species, which formerly lived in the Zoological Gardens, and is described in Proc. Zool. Soc., 1833, p. 81, weighed 289 lbs., the shell being 4 ft. 4½ in. in length (over the curve), and 4 ft. 9 in. in width.

the investigation of which I would particularly recommend to persons visiting Aldabra.

Mr. Salmon states that the male shows himself to be annoyed when the female is disturbed, and there is no doubt that he exhibits affection for her, as was especially evident on board the steamer, when he tried to break out of his cage as soon as he got sight of the female, who was transported in a separate cage. The circumstance that the two animals are a pair, increases the chances in favour of their being kept alive for a lengthened period. And they will be well worth all the care we can bestow on them, as it is extremely doubtful whether we shall ever succeed again in obtaining a pair of full-grown examples. The male is without doubt the largest and most powerful individual of its race, far exceeding in size any of the few other individuals kept in the Seychelles. Nor is it likely that in Aldabra itself a similarly large example should have succeeded in evading the search of the numerous crews which have landed there.

From the historical evidence given above, it is evident :

1. That the presence of the Gigantic Tortoises at two so distant stations as the Galapagos and Mascarenes cannot be accounted for by the agency of man, and therefore that these animals must be regarded as indigenous.

2. That, although frequently transported by the early navigators to distant and apparently suitable localities (Sandwich Islands, Masa Fuero, and Ceylon), they never established themselves permanently, but there is no evidence to show whether this failure is due to an innate inability of the species to become acclimatised when far removed from its native place, or to the destructiveness of the inhabitants of those localities.

3. That the different islands of the Galapagos group were inhabited by distinct races.

4. That possibly the animals even of so small a group as Aldabra were differentiated in the different islands.

5. That although these animals are still lingering in the Galapagos and Aldabra their numbers are yearly diminishing, and that their growth to perfect maturity is interrupted; that with respect to the races of the Galapagos Tortoise, the elucidation of the irdistinctive characters and original distribution, we are, and probably shall be, dependent chiefly on the materials already preserved in zoological museums.

6. That the Tortoises of Mauritius and Rodriguez are entirely extinct. It is probable that in some museums shells, or even entire animals of these once so numerous races exist, but it will be a matter of great difficulty to trace their origin; therefore our examination is limited at present to the osseous remains transmitted from the Mauritius and Rodriguez. ALBERT GÜNTHER

(*To be continued*)

NOTES

WE are glad to hear that both a zoological and botanical collector will form part of the retinue of the Prince of Wales, in his approaching visit to India.

DR. VOGEL (not the photographer of that name), the Director of the newly established "Sonnenwarte" of Berlin, is now in this country.

THE rate of propagation of the recent inundation waves in the south of France has been determined along the banks of the Garonne. It was found to have been no more than two miles an hour in a run of 140 miles in the district where the principal calamities occurred. The consequence is that an immense amount of property and life could have been saved if a system of warnings had been adopted. Wise as usual after the event, the authorities intend to establish such a system as is already in operation at Lyons for the Rhône, and at Paris for the Seine. In an article in the July number of *Symons's Monthly Meteorological Magazine*, on the French floods, is an interesting calculation which will give Londoners some idea of what a "flood" means. Supposing we had a flood in the Thames, it would cover on the south bank, the whole of Battersea Park, Lambeth, Southwark, Bermondsey, and Deptford; and on the north bank, Fulham, Chelsea, Brompton, Belgravia, Westminster, and St. James's Park; while, as for the new embankment, a steamer might ply over the top of it.

IT is suggested that the unusual violence of the floods on the continent are attributable not only to the abnormal amount of rain and the sudden melting of snow and ice in the mountain districts, but also to the increasing destruction of forests which is taking place in nearly every country. For some years past the violence of the spring and summer floods has been increasing, and it is remarkable that this increase in their force is contemporaneous with the gradual extinction of forests and woodlands. The existence of forests has a great effect in equalising the distribution of water, and in checking the too rapid melting of snow and ice under the influence of the summer heat. At the same time the growth of timber on hill sides prevents the rapid flow of surface-water which takes place where trees do not exist. The question of maintaining forests, instead of destroying them, without making provision for the future, is one which demands the serious attention of the governments of every country, and particularly of those countries where, by the existence of hills and mountains, and consequently rapid rivers, the liability to floods is increased.

WE have been informed that during the recent very bad weather there has been an unusual number of icebergs met with in the North Atlantic, and that fogs in Labrador and Newfoundland have been extraordinarily severe and frequent. It is to be hoped that some general inquiry into the recent peculiar weather and its accompaniments will be instituted; no doubt valuable results would be obtained.

THE Austrian Commission to the International Geographical Exhibition has intimated that they intend to present to the French Geographical Society all the books they are exhibiting. As this example will, we are informed, be followed by other Commissions, a magnificent Geographical Library will be one of the results of the meeting of the Congress.

THE work of the Sub-Wealden Exploration is temporarily arrested at 1,672 feet from increasing deposit from the sandy beds. The original problem was dependent on the opinion of geologists that palæozoic rocks would be found at a depth varying from 700 to 1,700 feet. So far, however, the strata are mesozoic; but the latest fossils give some indications of a palæozoic rock. Much hope is therefore entertained of solving the problem.

PARTS 19 to 24 of the quarto work published by authority of the Lords Commissioners of the Admiralty, on the Zoology of the Voyage of H.M.S. *Erebus* and *Terror*, conclude the descriptions of the Mammalia by the late Dr. J. E. Gray, F.R.S.; the Birds by Mr. R. B. Sharpe; the Reptiles by Dr. A. Günther, F.R.S.; and the Insecta by Mr. A. G. Butler. Part 20 is by Mr. E. J. Miers on the Crustacea, and Part 21 by Mr. E. A. Smith on the Mollusca.

THE Rev. E. Ledger, M.A., rector of Duxford, Cambridgeshire, was yesterday elected to the Gresham Professorship of Astronomy in the City of London. Mr. Ledger was a Carpenter and Beaufoy Scholar of the City of London School, and afterwards Fellow and Lecturer of Corpus Christi College, Cambridge. He was fourth Wrangler in 1863, and also University Scholar of the University of London.

AN International Horticultural Exhibition and Congress is to be held in Amsterdam in 1876, similar to the one held in Florence last year. A strong committee has been appointed,

who desire the co-operation of the various horticultural societies throughout Europe in making the undertaking as complete and successful as possible. The President is to be Mr. J. H. Krelage, and the Secretary Mr. H. Groenewegen.

Mr. Thiselton Dyer, in consequence of his recent appointment to Kew, has resigned the Professorship of Botany at the Royal Horticultural Society.

Dr. Hoffmann, of Giessen, contributes an interesting article on the influence of inland-water on the vegetation of shore-lands to the *Oesterreichisches Landwirthschaftliches Wochenblatt* of July 10. His object is to prove that large bodies of water tend to produce an equable climate, and that a large percentage of heat and light is due to the reflected rays of the sun from the surface of the water. To illustrate his argument he selects that part of the river Rhine which flows from east to west, from Biebrich to Niederwald, where the northern bank more particularly in the immediate vicinity of the water produces the best grapes in Germany. Moreover, he states that the fogs rising from the water in the month of May protect the tender shoots of the vine from being injured by late frosts. This, at any rate, does not agree with our experience in this country.

It is stated that, in consequence of pressure of business, the Government is not likely to be in a position, during the present session, to return any final answers to the applications for aid made on behalf of King's College, London; Owens College, Manchester; the University College of Wales; and other educational bodies throughout the country.

Lord Aberdare has been elected President of the Social Science Association for the ensuing year.

In a pit about half a mile east of Erith Railway Station, where an old and deserted bed of the Thames is excavated for brick earth, and which has yielded the bones of two species of British elephant and one of lion, Dr. Gladstone, F.R.S., was so fortunate as to find, on Saturday last, a large flint implement of palæolithic make. The implement is seven inches in length, slightly convex, and chipped on the outer curve with three longitudinal faces; consequently it has four working edges. At the butt end an echinus, or sea urchin, is embedded in the flint.

In some excavations which have recently been undertaken during the construction of the continuation of the Thames embankment westwards, some probably prehistoric remains have been brought to light, which include a human lower jawbone with all the teeth present. At about the same spot a flint knife was discovered and other animal remains, some mixed with freshwater shells.

In the Proceedings of the Bristol Naturalists' Society (Vol. I. Part ii.) will be found the translation, by Dr. Fripp, of a valuable paper by Dr. E. Abbe, of Jena, entitled, "A Contribution to the Theory of the Microscope, and the Nature of Microscopic Vision."

The University of California has organised a summer exploring party, which will be occupied about nine weeks in journeying through the Sierra Nevada Mountains in Mariposa, Mono, and Inyo counties, and will bestow particular attention to geology, palæontology, and mineralogy. The party will be in charge of Dr. Joseph Le Conte, assisted by Mr. Henry Edwards, Mr. F. P. M'Lean, and Mr. F. Slate.

Sir Charles Locock, Bart., F.R.S., First Physician-Accoucheur to the Queen, died on Friday last, at the age of seventy-six years.

The British Archæological Association meets this year at Evesham, on Monday, August 16, when the President, the Marquis of Hertford, will deliver the inaugural address.

A Reuter's telegram states that an attack has been made on the Palestine exploring party, none of whom have, however, been hurt. The assailants were repulsed.

The rector of the Catholic University of Louvain (Belgium) has gone to Paris in order to consult with the ecclesiastics now engaged in preparing to establish a Catholic University in that city. The site has been already chosen, and is close to the place where *La Bastille* was erected during the old Monarchy. The liberals are not likely to establish a University of their own, if the existing University satisfies their principal claims.

A capital weekly journal, the *Electrical News and Telegraphic Reporter*, whose first appearance we intimated a few weeks ago, has just completed the first month of its existence. It is edited with care and ability by Mr. Crookes, and is uniform in size and price with the *Chemical News*. In the number for July 22 there are nine articles of considerable scientific value and others of no less general interest. We notice especially the paper on Quadruplex Telegraphy and the Telegraph in China. The notes are interesting, and the reports of electrical science from the foreign journals are well done. We are glad to be able to bring this useful journal under the notice of our readers.

An examination will be held at Exeter College, Oxford, on Thursday Oct. 14, for the purpose of election to two scholarships in Natural Science, of the annual value of 80*l*. each, tenable for five years.

We have received the "Second Appendix" to the "Flora of Liverpool," issued by the members of the Field Club. It contains additional habitats for many species, and also includes several species not previously recorded as growing in the district, some of them of considerable rarity, as: *Ranunculus fluitans*, *Barbarea stricta*, *Carduus nutans*, *Doronicum Pardalianches*, *Cusenta Europæa*, *Mentha rubra*, *Stachys ambigua*, *Atriplex triangularis*, *Rinnex pratensis*, *Alisme natans*, *Carex divulsa*, *axillaris* and *fulva*. Local "floras" are becoming so numerous now, and the directions for finding certain plants so minute, that there is some point in the remark of a facetious foreign professor of botany, who said that we should soon have have all our British plants separately labelled. This defect (in our opinion) is rather conspicuous in the Appendix to the Flora of Liverpool. It may be desirable to know something about the number of individuals of exceedingly rare though undoubtedly indigenous species.

Mr. Dall has presented a report to the United States Coast Survey on the tides, currents, and meteorology of the Northern Pacific. He finds proof of the existence of a northerly current, denominated by him "the Alaska current," which had previously been surmised.

Vol. vi. of Mr. F. V. Hayden's Report of the U.S. Geological Survey consists of a monograph, by Mr. Leo Lesquereux on the Cretaceous Flora of the Western Territories, profusely illustrated. Mr. H. Gannett, under the same direction, has issued the third edition of a List of Elevations west of the Missouri River.

The additions to the Zoological Society's Gardens during the past week include, a Chimpanzee (*Troglodytes niger*) from W. Africa, presented by Capt. Lees, Govenor of Lagos, W. Africa; three Amherst Pheasants (*Thaumalea amherstiæ*); a Geoffroy's Blood Pheasant (*Ithaginis Geoffroyii*) and five Temminck's Tragopans (*Ceriornis Temminckii*) from China, deposited; a Sambur Deer (*Cervus aristotelis*), two Brown Indian Antelopes (*Tetraceros subquadricornutus*) from India, a Tora Antelope (*Alcelaphus tora*) from Upper Nubia, an Elate Hornbill (*Buceros elatus*), an Electric Silurus (*Melapterurus beninensis*) from W. Africa, a Naked-throated Bell Bird (*Chasmorhynchus nudicollis*), a Pectoral Tanager (*Ramphocœlus brasilius*), a Festive Tanager (*Calliste festiva*) from Brazil, purchased.

SOCIETIES AND ACADEMIES

London

Geological Society, June 23.*—Mr. John Evans, V.P.R.S., president, in the chair.—On the Granitoid and associated Metamorphic Rocks of the Lake-district, by J. Clifton Ward.

Part I. *On the Liquid Cavities in the Quartz-bearing Rocks of the Lake-district.*—The object of this paper was to examine into the evidence afforded by the liquid cavities of the granitoid rocks of the Lake-district, with reference to the pressure under which these rocks may have consolidated. In the first division of the subject the geological relations of the three granitic centres of the district were considered, and it was shown that these several granitic masses probably solidified at depths varying from 14,000 feet to 30,000 feet. The most probable *maximum* depth for the Skiddaw granite was stated as 30,000 feet; the *maximum* for the Eskdale granite 22,000 feet; and for the Shap granite 14,000 feet. These maximum depths were arrived at by estimating the greatest thickness of strata that were ever, at one time, accumulated above the horizon of the top of the Skiddaw slates. The mode of microscopic examination, together with a description of the precautions taken in measuring the relative sizes of the cavities and their contained vacuities, formed the second division of the paper. It was stated that all the measurements used in the calculations were made from cases in which the vacuity mixed freely in the liquid of the cavity, and an approximately *perfect* case for measurement was defined to be one in which the outline of the liquid cavity was sharply defined all round in one focus, and in which the vacuity moved freely to every part of the cavity *without going out of focus*. Then followed the general results of the examination. Restricting the measurements to such cases as those above mentioned, the results were found to be generally consistent with one another, and with those previously obtained by Mr. Sorby in his examination of other granitic districts. From the fact that the calculated pressure in feet of rock was in all cases greatly in excess of the pressure which could have resulted from the thickness of overlying rocks, it was inferred as probable that these granitic masses were not *directly* connected with volcanic action, by which the pressure might have been relieved, but that the surplus pressure was spent in the work of elevation and contortion of the overlying rocks. Microscopic, combined with field evidence, was thought to indicate that the Shap granite, though mainly formed at a depth similar to that at which the Eskdale granite consolidated, was yet itself finally *consolidated* at a much less depth, the mass having eaten its way upwards at a certain point, and perhaps representing an unsuccessful effort towards the formation of a volcanic centre. The examination showed that the *mean* of the pressures under which the Lake-district granites probably consolidated was nearly the same as the *mean* which Mr. Sorby arrived at for those of Cornwall. In conclusion the author stated that he wished these results to be considered as preliminary only, since the *complete* investigation would necessarily occupy far more time than was at his disposal; at the same time he ventured to hope that *general* accuracy was insured, while pointing to the many little-known causes which might affect the conclusions.

Part II. *On the Eskdale and Shap Granites, with their associated Metamorphic Rocks.*—The author brought forward evidence in this paper to prove the possibility of the formation of granite by the extreme metamorphism of volcanic rocks. The passage is shown in the field, and may be observed in a complete series of hand specimens. Frequently, indeed, the actual junction is well marked, but in other cases the transition is gradual; and there occur at some little distance from the main mass, inlying patches of what may be called bastard granite. The microscopic examination proves the passage from a distinctly fragmentary (ash) to a distinctly crystalline rock, and to granite itself. Also the chemical composition of the altered rocks agrees very closely with that of the granite. Both Eskdale and Shap granite were believed to have been formed *mainly* from the rocks of the volcanic series by metamorphism at considerable depths; but the granite of Shap was thought to be in great measure intrusive amongst those particular beds which are now seen around it. A decided increase in the proportion of phosphoric acid was noted in the volcanic rocks on approaching the granite, and a decrease in carbonic acid.

On the Correlation of the Deposits in Cefn and Pontnewydd Caves, with the Drifts of the neighbourhood, by Mr. D. Mackintosh. Believing that the time has arrived for making some attempt to correlate cavern-deposits with glacial and interglacial drifts, the author ventures to bring forward the results of a personal examination of the remnants of the deposits in Cefn and Pontnewydd caves, compared with old accounts given by Mr. Joshua Trimmer and others. He has been led to regard the following as the sequence of deposits before the caves were nearly cleared out (order ascending):—1. Loam with bones and smoothly rounded pebbles, nearly all local (cemented into conglomerate in Pontnewydd cave). As a few foreign pebbles of felstone have been found in this bed, it could not have been deposited by the adjacent river Elwy before the great glacial submergence; and the author gives reasons for believing that it was not introduced by a freshwater stream from the boulder-clay above in Post-glacial times, but that it may possibly represent the middle drift of the plains, and may have been washed in by the sea during the rise of the land. After emergence, and during a comparatively mild interglacial period, bones of animals may have been introduced by rain through fissures in the roof of the cave, and these may have become partly mixed up with the underlying pebbly deposit. 2. Stalagmite, from less than an inch to two feet in thickness, accumulated during a continuance of favourable conditions (apparently absent in Pontnewydd cave). Bones of animals were again brought in by rain or by hyænas, and were afterwards worked up into the following deposit:—3. Clay, with bones, angular and subangular fragments of limestone, pebbles of Denbighshire sandstone, felstone, &c. (palæolithic flint implements and a human tooth in Pontnewydd cave according to Prof. T. M'Kenny Hughes). This clay once filled the Cefn cave nearly to the roof. There are reasons for believing that it was principally introduced through the mouth of the cave, that it is of the same age with the neighbouring upper boulder-clay, and that it is not a freshwater redeposit of that clay. It was probably washed in during a second limited submergence. 4. Loam and coarse sand charged with minute fragments of sea-shells. Portions of this deposit may still be found in the Cefn cave; and it may have been introduced through fissures in the roof by the sea as the land was finally emerging.

Geological Notes from the State of New York, by Mr. T. G. B. Lloyd, C.E. The substance of this paper comprises notes, accompanied by drawings and sketches of various matters of geological interest which fell under the author's observation whilst residing some years ago in the State of New York. The different subjects are divided under the following heads:—(1) Groovings and channelings in limestone running across the bed of Black River at Watertown, Jefferson co. (2) Descriptions of the superficial beds of boulder-clay, sand, and gravel which were exposed to view in the district around the village of Theresa during the construction of the Black River and Morristown railroad. (3) A description, with a general and detailed drawing to scale, of a remarkable "Giant's Kettle" near Oxbow, in Jefferson co. (4) An account of some peculiar flower-pot-shaped blocks of sandstone discovered in a quarry of Potsdam sandstone at the village of Theresa. The author in conclusion refers to a statement in a paper on Niagara by Mr. Belt, F.G.S., published in the *Quart. Journ. of Science* for April 1875, in which it is stated that the sections described as occurring near the Falls are typical of the superficial beds that mantle the whole of the northern part of the State of New York and Ohio and much of Canada. He is unable to find any description of a deposit which bears a near resemblance to the boulder-clay occurring in the district around the village of Theresa, in the descriptions of various authors of the superficial deposits of the northern part of the State of New York and Canada. He therefore ventures to remark that no section can be considered as typical of the whole of the north part of the State of New York which does not recognise the existence of the deposit in question.

On a Vertebrate Fossil from the Gault of Folkestone, which also occurs in the Cambridge Greensand, by Prof. H. G. Seeley, F.L.S. The author describes a bone having the general form of an incisor tooth obtained from the Gault of Folkestone by Mr. J. S. Gardner, F.G.S. The flattened cylindrical end of a specimen from the Cambridge Greensand has been figured as a caudal vertebra of *Pterodactylus simus*. A microscopic section of the expanded end of a specimen from the Cambridge Greensand exhibits ordinary osseous tissue, showing that the fossil is probably a dermal spine from the tail of a Dinosaur. The Gault specimen is smaller than the examples from Cambridge.

Royal Horticultural Society, July 7.—Scientific Committee.—J. D. Hooker, F.R.S., in the chair.—A paper on the resting-spores of the potato disease was read by Worthington

* Continued from p. 243.

Smith, F.L.S. These were identified with the bodies which Mr. Berkeley had lately regarded as a species of *Protomyces*, and the cause of a new malady in the potato. The following are the principal points in this very important communication:—On receiving authentic specimens of diseased plants from Mr. Barron, Gardener-in-Chief to the Society, the brown spots on the potato-leaves at once called to mind the figures of some species of *Protomyces*, and the dimensions agreed tolerably well with some described plants of that genus, but the spots, when seen under a high power, appeared very unlike any fungus, and they were very sparingly mixed with other bodies much smaller in diameter, and with a greater external resemblance to true fungus spores. These latter spore-like bodies were of two sizes—one transparent and of exactly the same size as the cells of the leaf (and therefore very easily overlooked), and the other dark, reticulated, and much smaller. A few mycelial threads might be seen winding amongst the cellular tissue. The author's opinion, therefore, was soon formed that the "new" potato disease was no other than the old *Peronospora infestans* in an unusual and excited condition. That climatic conditions had thrown the growth of this fungus forward and out of season was probable; but the idea that the pest would not at length attack all and every sort of potato seemed unreasonable, though the more tender sorts might be the first to suffer. From day to day the diseased leaves and stems and tubers were kept between pieces of very wet calico, in plates under glass, and it was immediately noticed that the continued moisture greatly excited the growth of the mycelial threads. So rapid was now the growth of this mycelium, that after a week had elapsed some decayed parts of the lamina of the leaf were traversed in every direction by the spawn. In about ten days the mycelium produced a tolerably abundant crop, especially in the abortive tubers, of the two-sized bodies previously seen in the fresh leaves. The larger of these bodies Mr. Smith was disposed to consider the "oospore" of the potato fungus, and the smaller bodies as the "antheridia" of the same fungus, which are often terminal in position. The filaments of the latter are commonly much articulated, and sometimes more or less moniliform or necklace-like. Both oospore and antheridium are very similar in nature and size to those described as belonging to *Peronospora alsinearum* and *P. umbelliferarum*, and this is another reason (beyond the occurrence of undoubted *P. infestans* on potato-leaves at the beginning of June) why he was disposed to look upon these bodies as the oospore and antheridium of the potato fungus. The larger bodies are at first transparent, thin, pale brown, furnished with a thick dark outer wall, and filled with granules; at length a number (usually three) of vacuities or nuclei appear. The smaller bodies are darker in colour, and the external coat is marked with a few reticulations, possibly owing to the collapsing of the outer wall. At present he had been unable to detect any fecundating tube (described as belonging to the antheridium of other species of *Peronospora*), but he had observed the two bodies in contact in several instances. After fertilisation has taken place, the outer coat of the oospore enlarges, and appears to be cast off. Both antheridium and resting-spore are so slightly articulated to the threads on which they are borne that they are detached by the slightest touch, but with a little care it is not really difficult to see both bodies *in situ*; and my observations lead me to think that conjugation frequently takes place after both organs are quite free. The antheridia and oospores are best seen in the wettest and most thoroughly decomposing tuber, but they occur also in both the stem and leaf. The author was also disposed to regard Montagne's *Artotrogus* as identical with the resting-spore of *Peronospora infestans*, an opinion which had long been held by Mr. Berkeley.

PARIS

Academy of Sciences, July 19.—M. Frémy in the chair.—The following papers were read:—On M. Espy's meteorological theory, by M. Faye.—On the continuation which it will be necessary to make of experimental researches on plasticodynamics, by M. de Saint-Verant. This new branch of mechanics treats of the internal motions of solid bodies in a state of plasticity. M. Tresca added some remarks on the same subject.—Experimental and clinical considerations on the nervous system with regard to its function in actions governed by the sensitive, instinctive and intellectual faculties, as well as in the so-called voluntary locomotive actions, by M. Bouillaud. The author arrives at the following conclusions:—The cerebrum and the cerebellum are both absolutely necessary for all actions which are governed by the various faculties of mind or intelligence. The cerebellum is the seat of co-ordination of the movements of walking, the cerebrum being the seat of the co-ordinating centres of the movements necessary for the execution of a great number of intellectual actions, speech in particular.—On a distinction between natural and artificial organic products. The author repeats the distinction made by him in 1860, in reply to a statement by M. Schutzenberger. This distinction is that natural bodies are always unsymmetrical.—Observations relating to M. Hirn's communication of June 23. Importance of basing the new theory of heat on the hypothesis of the vibratory state of bodies, by M. A. Ledieu.—Note on the chronology and geography of the plague in the Caucasus, in Armenia, and in Anatolie during the first half of the nineteenth century, by M. J. D. Tholozan.—On the development of the spiny rays in the scale of *Gobius Niger*, by M. L. Vaillant.—On d'Arrest's periodic comet, by M. Leveau.—Observations of Jupiter's satellites during the oppositions of 1874 and 1875. Determination of their differences of aspect and of their variation of brilliancy, by M. Flammarion. In size the decreasing order is III., IV., I., II. Intrinsic luminosity for equal surfaces I., II., III., IV. Variability in decreasing order IV., I., II., III.—Note on magnetism; reply to an observation of M. Jamin, by M. J. M. Gaugain.—Oxy-uvitic and the cresol derived from it, by MM. A. Oppenheim and S. Pfaff. The cresol is metacresol.—On a compound of methyl oxide and hydrochloric acid, by M. C. Friedel.—On the diethylic ether of xanthoacetic acid, by MM. C. O. Cech and A. Steiner.—On the estimation of carbon disulphide in the sulphocarbonates of potassium and sodium, by MM. David and Rommier.—On the mode of action of the pillars of the diaphragm, by M. G. Carlet.—On the reproduction of eels, by M. C. Dareste.—The morphological elements of the oblong leaves of the monocotyledons, by M. D. Clos.—On a claim of priority relative to a fact of botanical geography, by M. Ch. Contejean.—During the meeting M. Mouchez was elected a member of the Astronomical section to replace the late M. Mathieu.

BOOKS AND PAMPHLETS RECEIVED

British.—Chambers' Encyclopædia. 10 vols., new and revised edition (W. and R. Chambers).—Reports of the Medical Officer of the Privy Council and Local Government Board. New Series, No. 3 (Spottiswoode).—On the Inequalities of the Earth's Surface viewed in connection with the Secular Cooling: Osmond Fisher, M.A. (Cambridge Philosophical Transactions).—Flora of Eastbourne: F. C. S. Roper, F.L.S. (Van Voorst).—Travels in Portugal: John Latouche (Ward, Lock, and Tyler)—Second Supplement to Watts's Dictionary of Chemistry (Longmans).—Transactions of the Manchester Geological Society, Vol. xiii. Part 10.—Health in the House: Catherine M. Buckton (Longmans).—Hydrology of South Africa: J. Croumbie Brown, LL.D. (H. S. King and Co.)—Rudiments of Geology: Samuel Sharp, F.S.A., F.G.S (E. Stanford).—The Skull and Brain; their Indications of Character and Anatomical Relations: Nicholas Morgan (Longmans). North Staffordshire Naturalists' Field Club Addresses, Papers, &c.—On the Sensations of Tone as a Physiological Basis for the Theory of Music, by H. Helmholtz; translated by A. J. Ellis, F.R.S. (Longmans).—Reports and Proceedings of the Miners' Association of Cornwall and Devon for 1874.
